LIST OF CONTRIBUTORS

Francisco J Aguilar, M D, Guatemala City, C A

Director of Laboratories and Professor of Parasitology, Medical School, San Carlos University of Guatemala Chief of Parasitological Institute, Public Health Service, Guatemala City

Floriano Paulo de Almeida, M D, São Paulo, Brazil, S A

Docent and Assistant in the Department of Microbiology of the School of Medicine, Professor of Microbiology, the School of Obstetrics University of São Paulo

Afranio do Amaral, B Sc & L, M D (Bahia), D Hyg & Trop Med (Harvard), São Paulo, Brazil, S A

Director, Butantan Institute (Retired), São Paulo, Founder and former Director, Antivenin Institute of America, Philadelphia Pennsylvania U S A, Vice President International Commission on Zoological Nomenclature England

Donald L Augustine, B S, Sc D, M A (Hon), Harvard University, Sc D (Hon), Macalester College, Boston, Massachusetts, U S A.

Professor of Tropical Public Health Harvard School of Public Health, Consultant in Comparative Pathology Children's Hospital, Boston Consultant to the United States Public Health Service

Frederik B Bang, A B, M D., Baltimore, Maryland, U S A

Formerly Major Army of the United States Associate Professor of Medicine, Johns Hopkins University School of Medicine Baltimore

Enrique Beltrán, M D., Acad. Prof Science, Nat, Hon M.Sc (Mexico), Mexico, D F, Mexico

Professor of Protozoology University of Mexico and Polytechnical Institute, Head, Department of Protozoology, Institute of Public Health and Tropical Diseases Mexico, Member, National Academy of Medicine Mexico

Luis Benitez Soto, M D, Mexico, D F, Mexico

Professor of Pathology, Military Medical School Mexico, formerly Associate Professor of Pathology, Medical School, and Associate Professor of Cancerology Medical School University of Mexico, formerly Director of Laboratories Public Health Department, Mexico, Colonel Medical Corps Mexican Army

Alfonso Bonilla-Naar, M D, Bogotá, Colombia, S A

Professor of Tropical Medicine Professor of Parasitology, National School of Medicine, Bogotá

Roy Edwin Butler, A B, M D, New Orleans, Louisiana, U S A

Senior Surgeon, United States Public Health Service, New Orleans

Gustavo Cardelle, M D, Havana, Cuba

Instructor in Clinical Pediatrics School of Medicine, University of Havana, Chief of Medicine Municipal Children's Hospital of Havana

Maximiliano Ruiz Castañeda, M D, Mexico, D F, Mexico

Director Department of Medical Research General Hospital, Mexico

Clement Clapton Chesterman, O B E, M D (London), M R C P, D T M & H (Cantab), London, England

Teacher of Tropical Medicine Middlesex Hospital Medical School, University of London, formerly Medical Missionary Baptist Missionary Society Belgian Congo

Antonio Clerch Rius, M D, Havana, Cuba

Director National Institute of Health of Cuba Medical School, University of Havana

Joseph Wesley Colvin, A B, M D, Fort Worth, Texas, U S A

Formerly Lieutenant Commander M C, United States Navy formerly Head, Department of Tropical Medicine United States Naval Medical School, Bethesda, Maryland, Harris Memorial Methodist Hospital, Fort Worth

Arturo Curbelo Hernandez, M D, Havana, Cuba

Associate Professor of Bacteriology School of Medicine University of Havana, formerly Director of National Institute of Health Havana formerly Director, Finlay Institute, Havana Consulting Bacteriologist Municipal Children's Hospital Havana, Hospital Nacional Calixto Garcia Havana Hospital Ntra Sra de las Mercedes, Havana

Anthony Donovan, A B, M D, Lima, Peru, S A

Senior Surgeon United States Public Health Service Chief, Zone Office, Pan American Sanitary Bureau Lima

Oscar Felsenfeld, M D, Chicago, Illinois, U S A

Director of Bacteriology Hektoen Institute for Medical Research of the Cook County Hospital Chicago Professorial Lecturer, University of Illinois College of Medicine and the Graduate College, Chicago

Lee Foshay, M D, Cincinnati, Ohio, U S A

Professor of Bacteriology College of Medicine, University of Cincinnati

R B H Gradwohl, M D, Sc D, F R S T M & H (London), F A P H A, Commander, M C, U S N R (Retired), St Louis, Missouri, U S A

Pathologist to Christian Hospital, St Louis, Director, Gradwohl School of Laboratory and X Ray Technique, St Louis

Morris Greenberg, A B, M S, M D, New York, New York, U S A

Director, Bureau of Preventable Diseases New York City Department of Health, Lecturer in Epidemiology, Columbia University New York.

Robert B Greenblatt, B A, M D, C M, Augusta, Georgia, U S A

Professor of Endocrinology, University of Georgia School of Medicine, Augusta

Hernando Groot, B S (National School of Commerce, Bogota), M D (National University, Bogotá), M P H (cum laude) (Harvard University), Bogota, Colombia, S A

Director of the Army Laboratories, Bogota *Professor of Parasitology and Tropical Medicine, School of Medicine, University of Javeriana, Bogota, formerly Director of* the Commission for the Study of Carrión's Disease Pasto, Colombia *formerly Director* of the Narino Public Health Laboratory, Pasto Colombia

Sachiko Janet Ishihara, B S, Chicago, Illinois, U S A

Microbiologist in Charge, I F Volini Memorial Antibiotics Research Laboratories of the Cook County Hospital, Chicago

Philip Herman Hartz, M D, Curaçao, Dutch West Indies

Pathologist, Public Health Service, Curaçao

Edward Henderson, M D, Bloomfield, New Jersey, U S A

Director of Clinical Research, Schering Corporation, Director Schering International Institute for Medical Research, Bloomfield

Alfred E A Hudson, B A, B Sc, M Sc, M P H, Major, M S C (Retired), United States Army, Goldsboro, North Carolina, U S A

Juan A Jimenez, M D, Havana, Cuba

Instructor, Department of Clinical Medicine School of Medicine, University of Havana *formerly* Pathologist, Municipal Children's Hospital of Havana

Pedro Kouri, M D, Havana, Cuba

Director Institute of Tropical Medicine Professor of Parasitology and Tropical Diseases, Vice Dean of the School of Medicine University of Havana Member of the Board of Directors Summer School, Havana University Founder Director of *Revista de Medicina Tropical y Parasitología* and of Laboratorios Kuba

Willem Kouwenaar, M D, Amsterdam, Netherlands

Professor of Tropical Hygiene University of Amsterdam Chief Division of Tropical Hygiene, Institute of Tropical Hygiene Department of the Royal Institute of the Indies, formerly Director of the Pathological Laboratory Medan Sumatra

Aram A Krajian, Sc D, Los Angeles, California, U S A

Honorary Member of Congress of Medicine of Mexico

Francisco Leon Blanco, M D, Havana, Cuba

Chief Pathologist to the Hospital Frevre de Andrade Havana

Atilio Macchiavello, M D, D P H, Alexandria, Egypt

Planning Officer Eastern Mediterranean Regional Office World Health Organization Professor of Hygiene and Preventive Medicine University of Chile Santiago, Chile S A formerly Consulting Epidemiologist Pan American Sanitary Bureau Lima Peru S A, *formerly* Director General of Health Santiago Chile *formerly* Professor of Tropical Medicine, Post Graduate School, University of Guayaquil Guayaquil Ecuador S A, *formerly* Professor of Epidemiology and Biostatistics, School of Hygiene, University of Chile, Santiago Chile

†Salvador Mazza, M D , Buenos Aires, Argentina, S A

DEDICATED

To those who toil in the heat and sweat of the tropical plantations and tropically located industrial enterprises to those who enter the jungle and the desert to bring health and progress to the native inhabitants to those rural workers and village physicians whose only information on this subject must necessarily be obtained from a comprehensive manual to the medical men of the Armed Forces who enter tropical territories and seriously prepare to safeguard their troops against the diseases of the land and to those who wish to familiarize themselves with the great problems presented by the Tropics

FOREWORD

With modern methods of communication and also as a result of the large numbers of men from the temperate zones who spent considerable periods in the Tropics during World War II, tropical medicine has assumed an importance greater than at any time in the whole history of medicine. Many advances and discoveries have also been made in this field in recent years. The literature of tropical medicine is constantly being increased. Preventive tropical medicine is a matter of great urgency in our present troubled world conditions. This textbook is of particular interest in that it is largely a production of Pan American authors in that leaders in the various fields of tropical medicine in North, Central, and South America have collaborated in its production. It represents a valuable addition to the many fine works on tropical medicine. As a textbook it will be extremely valuable.

Ross T McIntire
Vice Admiral Medical Corps
United States Navy Retired

PREFACE

The Editors present to the English-speaking scientific world this book on *Clinical Tropical Medicine* written by fifty-seven authors The variety and diversity in concept opinion and method of approach apparent in every chapter of the book begin with the personal training and individualities of the Editors One (R B H G) born reared and educated in the United States with many years of European postgraduate work including studies at the Hamburg Institute of Tropical Medicine wrote from his experiences in the United States Navy and his travels Another (L B S) a son of Latin America lives works and teaches in Mexico representing the views of Central and South America Finally the third (O F) a Continental European by upbringing but an American by choice is making every effort to synthesize the teachings of his West European masters with the achievements of the New World

The freedom of expression which the Editors maintained for themselves has been reserved also for the contributors While certain requirements were necessarily observed by each writer there was no curtailment of ideas and concepts The number of pages had to be limited but not the internal arrangements of the chapters thus no objection was raised if an author wished to stress one or another part of his contribution or desired to express an unusual opinion

While the Editors believe in the great value of contributions from established authors they feel that the younger writers should also have their say It was for this reason that some authors were selected whose qualifications were ample but whose claims to international recognition had not yet been established We hope that the results will prove satisfactory

In selecting the authors of this book every possible effort was made to appoint only those with actual clinical experience with the diseases with which their writing was concerned In other words the compilation of literature and findings of a variety of experts was not what was desired rather it was desirable to have clinical and laboratory experiences recorded which came out of daily contact with the diseases in question It is not given to any expert on tropical medicine to be familiar with all the diseases of the Tropics This book pretends to be a record of specialistic knowledge

The material and scope of subject matter which should form a book on tropical medicine were much debated in preliminary discussions After serious consideration the Editors decided that climatic nutritional and transmissible diseases should be stressed with special emphasis on those which with a few exceptions such as dysenteric disorders constitute a major problem only in the Tropics Smallpox rabies coccidioidosis etc which are often included in handbooks of tropical medicine do not appear in this volume

The idea for the present book was conceived in 1944. It was originally intended to be a Pan American work. Delays in the publication carried it over into postwar years. While this necessitated bringing many chapters up to date, it also permitted the Editors to include valuable contributions from Dutch, English, and Indian authors which could not have been secured during *World War II*.

In the preparation of this type of book, there were many difficulties due to the fact that a great deal of the manuscript was submitted in foreign languages. In correcting translations, in checking dosages of drugs, references to the literature, style, spelling, etc., the admirable literary and editorial talents of our assistant, Mrs. Addine G. Erskine, must be paid a special tribute. All this, together with her careful preparation of the index, merits our deepest appreciation and thanks.

The Editors wish to express their deepest gratitude to all contributors.

CLINICAL TROPICAL MEDICINE

CHAPTER I

INTRODUCTION TO TROPICAL MEDICINE

R B H Gradwohl

Tropical medicine has naturally always been an important part of the practice of those who dwell in tropical regions it has lately assumed an important place in the practice of many physicians who live far from the tropics since many of these so called exotic diseases may also occur in temperate zones or may be imported by reason of today s rapid communications The reader will note elsewhere (Chapter 63) important information about diseases of the temperate zone as they manifest themselves in the tropics Here and there he will find frequent reference to the diseases of the tropics as they manifest themselves in more temperate zones Again there are certain diseases which are tropical which are distinctly *not* tropical—malaria and amebic dysentery This brings us to a consideration of the meaning of the term 'tropical medicine '

Much debate has waged about the propriety of this term Col F R Dieuaide (1945) then Chief of the Tropical Disease Treatment Branch in the Office of the Surgeon General United States Army stated that there are very few true tropical diseases and that the classification of world wide diseases such as plague and cholera is quite dangerous since it may result in widespread ignorance of their nature and general lack of skill in their control Again referring to malaria which is commonly called a tropical disease it is a very important disease in the United States and is not necessarily tropical Relapsing fevers also are tropical only in small part Kala azar a so called tropical disease is very common in Peiping China a latitude of 42 degrees north definitely not a tropical area Beriberi a so called tropical disease is found outside the tropics Neither bacillary nor amebic dysentery is confined to the tropics This author believes that tropical medicine so called has only a feeble and inaccurate significance meaning at best diseases not now common in Western Europe or North America He insists upon the point that there are peculiarities of disease in relation to topography climate and the distribution of pathogenic and disease transmitting organisms such subjects are part of pathology Interrelated in many ways are the effects of social conditions as they occur in various regions of regional food habits and food supplies and of hereditary racial traits He offers the term geopathology to cover this question There is considerable reason to consider this writer's suggestions very seriously The Continental experts have used the terms 'exotic diseases' and diseases of warm countries to cover this branch of medicine In the meantime we shall continue to use the old term tropical medicine" until full debate and more appropriate conclusions are drawn therefrom

As far as the United States is concerned the need for adequate facilities for the study of tropical diseases became painfully evident with the outbreak of World War II A synopsis of prevailing conditions is to be found in a monograph issued by The American Foundation for Tropical Medicine and the Liberian Institute of the American Foundation for Tropical Medicine * This society was organized and incorporated in the state of New York in 1940 It has ever since its foundation aided in the development of broad interest in tropical medicine In its pamphlet it is stated that following Pearl Harbor, a survey by Army and Navy medical services revealed only twenty four civilian doctors in the United States available for service with sufficient background to be useful in training medical men in tropical medicine While good work was done with this limited personnel they properly stated that two additional steps would have to be taken before this country would cease to lag behind and attain a ranking position in tropical medicine (1) establishment of a graduate school like the London School of Tropical Medicine and (2) the establishment of a research center in the tropics where scientists could do research work and students could be trained in the natural environment of true tropical diseases Such a research institute has been established through a gift of Mr Harvey S Firestone Jr for the construction and equipment of a research institute in Liberia West Africa

It was stipulated that at least ten leading university medical schools in the United States should agree to utilize the Institute for research and graduate training and that the Institute facilities be made available for all who are qualified without distinction of race, creed or color

The following universities have signified their interest in participating in the Institute s program and have each designated a representative to serve on the Scientific Advisory Committee

Bowman Gray School of Medicine of Wake Forest College
Columbia University School of Medicine
Duke University School of Medicine
Harvard University School of Medicine
Howard University School of Medicine
Johns Hopkins School of Medicine
Long Island School of Medicine
Meharry School of Medicine
New York University School of Medicine
University of California School of Medicine
University of Chicago School of Medicine
University of Michigan School of Medicine
University of Pennsylvania School of Medicine
University of Southern California School of Medicine
Stanford University School of Medicine
Tulane University School of Medicine

Liberia is just two flying days from New York and offers ample facilities for the study of tropical disease The Institute aims to take up three problems (1) diseases of man (2) diseases of domestic animals and (3) production of staple food crops

Thus the development of interest and progress in tropical diseases has been given a tremendous impetus by the foundation of the Institute There remains one more step in

*276 Madison Ave New York N Y

the United States, and that is the organization of strong departments of tropical medicine in various university medical schools Tulane, Harvard, Michigan, Johns Hopkins, California, and others are now making this effort There is every reason to believe that the training of medical students in the future in this country will be ample and will well cover this hitherto neglected field

With reference to adequate schools for research in tropical medicine, attention is called to the School of Tropical Medicine created by joint resolution of the legislature of Puerto Rico of June 23, 1924, which transferred to the school all the properties of the former Institute of Tropical Medicine and Hygiene A plan of cooperation between the University of Puerto Rico and Columbia University of New York for the operation of the school was worked out in conferences between representatives of the two universities in 1925 and was put in operation in 1926 According to this agreement the authority to determine the educational policy of the school and to make nominations to its faculty was delegated to Columbia University, subject to the approval of the special board of trustees In other respects, the school was operated as a semiautonomous unit of the University of Puerto Rico The primary aim of the School of Tropical Medicine in Puerto Rico is research, but it also offers opportunity to study in a tropical environment the cause and prevention of that large and ill defined group of disorders known as tropical diseases and, at the same time to observe the influence of tropical conditions on disease in general Puerto Rico offers special advantages as a site for such an institution As part of the United States, the island has unusually close cultural and commercial relations with the mainland and Canada The distance from New York is only 1,330 miles, less than four days by steamer and one day by airplane The island is a logical meeting place for English , Spanish , and Portuguese speaking investigators and students

The School of Tropical Medicine of San Juan was the first of its kind to be established in the Americas This school has well equipped laboratories for bacteriology, pathology, clinical medicine, chemistry, medical mycology and dermatology, and medical zoology The laboratories are modern in construction and contain all the conveniences necessary in carrying foward a well rounded research program In addition, there are teaching laboratories of fifty student capacity for the study of bacteriology, parasitology, and clinical pathology The official publication of the School of Tropical Medicine is the *Puerto Rico Journal of Public Health and Tropical Medicine*, printed as a quarterly in English and Spanish by Columbia University Press, of New York City, in cooperation with the Insular Department of Health

Adjoining the school is the sixty bed University Hospital, devoted mainly to the diagnosis and treatment of special diseases of the tropics and operated as the school's chief teaching and research clinic The first floor is given over to a well organized clinic for the out patient department, essentially in providing the facilities necessary in the selection of cases clinical pathology laboratory and x ray and urological divisions, together with the administrative and record offices There are courses in public health, but the courses offered are planned primarily for graduates in medicine who wish special training in tropical medicine and hygiene The degree of Doctor of Medicine from an approved medical school or satisfactory evidence of adequate preparation for the courses which the applicant desires is required in each case Women are admitted on the same terms as men

The last director of this school was Prof P Morales Otero Graduates in medicine will find in the School of Tropical Medicine at San Juan, Puerto Rico the proper environment and facilities for carrying out research on all tropical diseases *

* [illegible] of Tropical Medicine at San Juan [illegible] Legislature of 1949 dissolved the [illegible] bia University and established a [illegible] using the present facilities and [illegible] usual but the main aim for the

The College of Medical Evangelists has recently announced that a School of Tropical and Preventive Medicine is to be developed at *Loma Linda Calif*. It will operate in conjunction with the School of Medicine. Medical graduates and undergraduates will be given training in tropical medicine with emphasis on preventive aspects. Special short courses will be given for nonmedical missionaries preparatory to their departure for overseas posts. Dr Harold N Mozar has been named director of this new unit. He was director of the United States Army's World War II School of Tropical Medicine for overseas forces in New Guinea and Chief of the Communicable Diseases Section of the 47th General Hospital.

Getting back to World War II, our fighting forces soon found themselves scattered over a vast territory, much of which was tropical. Acquaintance with many diseases hitherto unknown to the American military medical officer was gradually acquired. A number of important scientific studies were made in the field on malaria, schistosomiasis, amebiasis, trypanosomiasis and other tropical diseases. Special hospitals and organizations were soon formed to care for many of the victims of these diseases.

With the termination of hostilities, the important question arose as to the probability of transmission of many diseases of the tropics from the sick veteran to the healthy civilian population. Fortunately many of the usual vectors of these diseases are not ordinarily found in our country so that inoculation of new victims from residual cases seems remote. This does not obtain with water borne and food borne diseases. Nevertheless, the importance of recognition of the symptomatology of such diseases by civilian physicians is still very great. Medical education is still called for with respect to tropical diseases. Again as it has truly been said, the period of incubation of many tropical diseases is often longer than the time required to fly completely around the world, therefore the possibility of direct importation of many diseases by flying Americans or foreigners is quite manifest. A man might land in New York City and come down with a severe and comatose attack of cerebral malaria and it might be unrecognized until autopsy reveals the true diagnosis. Medical records show that this occurred twice in New York City in recent years so the need for alertness in diagnosis of such diseases still obtains. In other words every practicing physician must know tropical medicine.

As far as literature is concerned there are many excellent periodicals devoted to the study of tropical diseases notably the *Transactions of the Royal Society of Tropical Medicine and Hygiene* the *American Journal of Tropical Medicine* *The Journal of Tropical Medicine and Hygiene* (London), *Quarterly Journal of Tropical Medicine and Hygiene (Documenta Neerlandica et Indonesica de Morbis Tropicis)* (Amsterdam). There have been many excellent text books written on this and allied subjects.

My early recollection is that of an old reference book by Martin Mayer entitled *Exotische Krankheiten*. Another which was quite useful to me while working in the Hamburg Institute of Tropical Diseases was *Krankheiten und Hygiene der warmen Länder* by Ruge, Muhlens and zur Werth. The late Admiral Stitt wrote a book entitled *Diagnosis, Prevention and Treatment of Tropical Diseases* which has passed through several editions and is a classic. The late C M Wenyon of the London School of Tropical Medicine, wrote a book called *Protozoology* which gives important underlying information on this subject. My former teacher at the Hamburg Institute Eduard Reichenow, wrote with Doerflein *Lehrbuch der Protozoenkunde*. The French text by Neveu Lemaire entitled *Traite d Helminthologie Medicale et Veterinaire* is another classic. Sir Philip Manson Bahr's textbook entitled *Manson's Tropical Diseases* has passed through thirteen editions, which is sufficient proof of its great

value Z Taylor Berkovitz' *Clinical Tropical Medicine* was a valuable undertaking and so are Faust's excellent treatise on *Human Helminthology* Craig's *Laboratory Diagnosis of Protozoan Diseases* and Belding's *Textbook of Clinical Parasitology* A remarkably useful book is that by J E Ash and S Spitz *Pathology of Tropical Diseases* During the war, Mackie Hunter and Worth issued the excellent volume entitled *A Manual of Tropical Medicine* written under the auspices of the Division of Medical Sciences of the National Research Council More recently Dubois and van den Berghe the well known Dutch investigators have issued their book entitled *Diseases of the Warm Climates* Another interesting and worthwhile volume is that by L. Everhard Napier entitled *The Principles and Practice of Tropical Medicine*

We now come to the present volume which is by international authors This book was organized and thought out by the writer in conjunction with Luis Benitez Soto and Oscar Felsenfeld It was thought that a book by international authorities from men who had had actual experience with the subjects in their respective chapters would prove a valuable addition to the literature This book is intended to be a guidebook for those practicing medicine in the tropics as well as for those in temperate zones who are forced to face the issue of picking out from an assembly of temperate zone diseases those which originate in the tropics or which have been transmitted from the tropics to this and other temperate zone countries

It is a well known fact that two diseases have been brought back by servicemen returning from the Pacific Islands from the China Burma India theater and from the Middle East These two diseases are amebic dysentery and hookworm T T Mackie has stated that of the veterans treated at his School of Medicine 61 per cent had parasitic infection of which 36 per cent were amebic dysentery and 10 per cent hookworm Mackie states that he estimates there are about one million infected veterans and that it is very important to train more physicians and laboratory specialists in tropical medicine

With respect to malaria which is both a tropical and a temperate zone disease reference is made to the presidential address of E Harold Hinman President of the National Malaria Society (1949) The National Malaria Society is an outgrowth of the National Malaria Committee Hinman gives the details of the history of this organization which are very interesting because the activities of this Society are intimately bound up with the campaign against malaria in this country To summarize a resolution was adopted before the Second Pan American Scientific Congress Washington D C Jan 7 1916 as follows

> That all American countries inaugurate a well considered plan of malaria rad at and control based upon the principle that the disease is preventable to a much greater degree than has thus far been achieved and that the education of the public in the elementary facts of malaria is of the first order of importance to the country's concern

The National Committee on Malaria was then formed whose objectives were (a) to stimulate interest in malaria problems (b) to serve as a medium through which societies and individuals may become identified with the study and prevention of the disease and (c) to coordinate the efforts of these

agencies with constituted federal state and local authorities The first meeting of the Committee was held at Memphis Tenn Nov 12 to 15 1917, in conjunction with the meeting of the Southern Medical Association Subsequent meetings were held in conjunction with this Association Since malaria attains its highest level of endemicity in the United States in the southeastern section this was indeed a fortunate organizational arrangement

The National Malaria Committee met for twenty five years and was succeeded by the National Malaria Society Just a little over fifty years ago in August 1897 Ross in India discovered the mechanism of the transmission of malaria which permitted a sound epidemiologic approach to the control of this devastating disease The technics for antimosquito programs developed very promptly including utilization of petroleum oil drainage filling screening etc By the onset of World War I extensive malaria control projects had been initiated in the southern United States by the United States Public Health Service and the International Health Board and the disease was recognized as preventable

Hinman called attention to the fact that with the millions of men returning from active duty in malarious areas of the tropics there was serious apprehension that malaria in the United States which had been steadily declining might flare up in a widespread manner throughout a great portion of the United States Despite numerous relapses among veterans in areas with substantial anophelism fortunately these fears were unfounded

There has been a general decline of malaria in this country which was believed to have begun during the last quarter of the nineteenth century In a letter to Dr Paul F Russell on Dec 12 1947 the president of the National Malaria Society stated

> It is becoming evident that malaria as a public health problem within the continental United States may disappear largely within the next few years This of course does not indicate that the United States will lose any of its concern in the control of malaria for it will have to maintain a program of surveillance and emergency control within its continental borders and it is not likely that within such a brief period the interest in the control of malaria will diminish greatly in many of the tropical countries of the world in which the United States has vital interests. In view of the homogeneity of interests of the membership of the National Malaria Society which is quite unusual in view of the heterogeneity of their professional background it is believed that it would be most undesirable to countenance the possibility that our membership might disintegrate and that no adequate provision be made for retaining the professional contacts which have been so useful in the past

In reference to the future Hinman in the presidential address stated that Russell had listed six very specific reasons for insisting upon the continuing importance of malaria in the United States National defense programs must contemplate the possibility of coping with malarious areas the acute world food shortage is intensified by areas undeveloped largely because of malaria, American business is expanding into malarious countries and is concerned with the efficiency of malaria control all our imports from malari

ous countries carry a hidden "malaria tax," our exports to malarious countries are restricted because malaria depresses the economic levels and finally there is a need to prevent the resurgence of malaria in our own country

It is safe to conclude that while malaria is definitely on the downgrade in this country the above remarks of Hinman indicate that we must continue to be alert in destruction of anophelism and in carrying out preventive measures in all parts of the world with which we are economically and culturally concerned

It is difficult to realize the extent of parasitic disease in this world both in and out of tropical areas The presidential address of Dr Norman R Stoll, of the Rockefeller Institute for Medical Research Princeton N J before the American Society of Parasitologists Dec 27 1946 entitled "This Wormy World" gives data that Stoll compiled on the prevalence of parasitic disease that will astonish the uninformed

The following figures are given by Stoll It is generally taken as a statistical fact that there are about 2 166 million people on the entire globe Taking Trichinella as a well known parasite there are about 500 million people in Europe including Russia with an average diaphragm infection rate of as low as 1 per cent (and this is much higher than prewar indices) that would mean that there are about 5 million cases in that area There are about one million cases in Central and South America Mazzotti of the Institute of Tropical Diseases and Public Health of Mexico estimates that there are 12 per cent Trichinella infections in Mexico City In Canada it is estimated that there are about 100 000 cases and in the United States one in six Americans is affected or about 21 million cases Hall and Collins emphasized that "the United States has the greatest problem of trichinosis of any country in the world" Quoting again from Stoll there are 39 million *Taenia saginata* (the beef tapeworm) infections most ascribed to Africa and the U S S R but less than 3 million *Taenia solium* (pork tapeworm) infections with nearly a half in Russia There are less than 100 000 cases of hydatid infection with South America leading There are 20 million cases of *Hymenolepis nana* infection two thirds of them in Asia There is a world total of 10 million cases of *Diphyllobothrium latum* infection with 3 million in the Baltic littoral northern Russia and U S S R in Asia

Of fish transmitted trematodes there are 19 million cases of *Clonorchis sinensis* (liver fluke) infection confined to Asia and there are indications of one million cases of the related *Opisthorchis felineus* infection confined to fisher folk in East Prussia the Dnieper River basin and northern Sverdlorsk in Asiatic U S S R There are about a few hundred thousand cases of fishborne intestinal flukes the Metagonimus and Heterophyes and an equal number of Echinostoma and Gastrodiscoides

The large intestinal fluke *Fasciolopsis buski* confined to Asia is responsible for 10 million cases about half of which are in the Chekiang endemic center There are no more than 100 000 cases of *Fasciola hepatica* infection There are about several hundred thousand cases of *Dicrocoelium dendriticum* infection in man found especially in the Stalingrad and Transcaucasus regions Regarding

Paragonimus westermani cases there are about 3 million infections of this lung fluke in Asia and a few thousand in West Africa. Of these trematode infections altogether there are about 34 million cases. The schistosomes are responsible for more than three times as many additional trematode infections with *Schistosoma japonicum infections the most numerous*. There are about 46 million cases of this infection. It is endemic in the Yangtze valley. Twenty per cent of the inhabitants of Chinese provinces in this valley are infected, 10 per cent in other Chinese provinces and Japanese prefectures and 30 per cent *in the Philippine Islands of Leyte, Samar, Mindoro and Mindanao*—a grand total of 46 million people. In some places in East Africa there is a 50 per cent incidence. Scott estimates 6 million are infected in Egypt; there are about 200 000 cases in the Near East, a few thousand in Europe, a grand total of 39 million bilharzia infected people.

Schistosoma mansoni is the most dispersed of the three schistosomes of man. It is found in the equatorial region of Africa, a band of infection from northern *Nigeria westward, with Scott's 3 million cases in Egypt, making a total of 23* million in Africa. There is a third of a million in the West Indies, 30,000 cases in Venezuela according to Scott, and nearly 6 million in northeastern Brazil. This gives 29 million cases altogether, or 114 million cases with all three schistosomes.

Regarding the guinea worm and the filariids there are about 27 million cases of *Dracunculus medinensis* in India. In Afghanistan, Iran, Arabia and southwestern U S S R in Asia there are 5 million more cases of the "fiery serpent." The African endemic areas furnish 15 million cases. The world has 48 million guinea worm cases.

Onchocerca is localized on the Pacific slopes of three states in Guatemala and two states of Mexico. *It is found in Africa in the zone from Sierra Leone* eastward. The world total does not exceed 20 million cases of infection.

There are about 7 million cases of *Mansonella ozzardi* infection in Central and South America. There are 27 million cases of *Acanthocheilonema perstans* infection in Africa, South America and Dutch New Guinea. There are 13 million cases of *Loa loa* infection in Africa. These four filarial forms conveyed by Simulium, Culicoides and Chrysops parasitize 67 million people.

As for the Wuchereria, Stoll does not distinguish in his analyses between *Wuchereria bancrofti* and *Wuchereria malayi*. They and their mosquito vectors are found throughout the tropical world. He believes that all the endemic areas are filariated, thus giving an infection rate of 758 million people, about one-third of the population of the globe.

Coming nearer home we may discuss a very common worm found in great numbers in this country, namely the Enterobius. In North America and Europe including U S S R the total number of infections reaches 18 and 87 million.

Some nematodes contribute over half of the helminthiases of man. Discussing *Ancylostoma duodenale* Stoll showed that by education and actual attack the number of hookworm infected Americans had decreased from 4½ mil

lion to 1¾ million between 1910 and 1935 Our present figures on hookworm infections are as follows from one to a few million in Oceania Europe North America and the USSR up to 359 million in Asia including Japan the Philippines and Dutch East Indies The total number of cases for the world is 457 million

Ascaris infections in North America total 3 million in Central and South America 14 times as many in Africa nearly 60 million in the world 644 million—these with hookworm representing about half of man s helminthiases The world total Trichuris infections comes to 355 million Strongyloides infections in Asia and Central and South America make a world total of 35 million cases

After surveying and emphasizing these figures Stoll estimates that it is possible to reduce the 3 000 million human cases of helminthiases by the year 2000 when the world population will reach the figure of 3 300 million inhabitants by the following ways

1 By applying and strengthening the teaching of the nuclear principles that apply in the field of parasitology

2 By encouraging by precept and example a shortening of the usual lag period in getting acceptable improvements in ideas through to where they will do the most good and by being less tolerant when the lag seems unnecessarily long

3 By sharpening the tools for attacking the helminthiases of man Against the intestinal worms education sanitation and treatment must be considered New chemotherapeutic preparations are desirable

These figures and conclusions of Stoll still further prove the necessity for medical men of all climes to acquaint themselves with the problems of tropical medicine

Insofar as tropical medicine and diseases of the temperature zone are concerned I cannot refrain from quoting (paraphrasing) at great length from Sir Philip Manson Bahr s presidential address before the Royal Society of Tropical Medicine and Hygiene in 1947 In this address entitled The Practice of Tropical Medicine in London Sir Philip Manson Bahr in most detailed manner narrated the types of cases about which he had been consulted in London the difficulties in diagnosis and the manner in which diseases of the temperate and tropical zones were intermingled and mistaken one for the other He called attention to the fact that pyonephrosis may resemble malaria He cited a case of a man who came by air from India to London because of malaria associated with renal symptoms In this case the true diagnosis was made the patient responded to blood transfusions and mandelic acid returned to India and remained well The splenomegaly mistakenly attributed to malaria was probably due to *Escherichia coli* septicemia In a number of cases suspected of malaria some other disease condition was found He reported a case of a woman who was referred to him because of ptosis of the spleen She had spent most of her life in India and had suffered severely from malaria She was treated in England with Atabrine and was highly

pigmented The large hard moveable mass with a sharp edge jutting out at the level of the umbilicus and extending *into the left iliac fossa* proved to be an inoperable gastric carcinoma He called attention to the fact that malarial cachexia may be mistaken for Addison's disease Manson Bahr further spoke of the effects of quinine *producing an acute hemolysis* which may be a precipitating factor in attacks of blackwater fever He warned practitioners that *kala azar* while *infrequent* in European patients may actually be seen far away from its *normal habitat* *In these cases* the appearance of the patient is different from that of the malaria patient The eye has a different look — not quite the shining penetrating gaze of the patient with malarial cachexia The splenic dullness *extends above* the costal margin and there may be some edema of the legs He reports a case of tuberculosis which resembled kala azar

Sir Philip Manson Bahr formulated some generalizations about amebiasis as it is seen in temperate zones such as London England First there exists a good deal of wishful thinking which tends to magnify the numbers of potential amebic cases Second there exists a wishful willingness to ascribe pathogenic properties to any species of ameba found in the feces Third acute abdominal pain and extreme meteorism are not features of intestinal amebiasis Fourth acute onset febrile attacks and vomiting are not characteristic of amebic dysentery which is usually apyrexial Fifth severe anemia of the pernicious type is not an accompaniment of amebic dysentery Sixth as compared with bacillary dysentery tenesmus is infrequent while loss of weight is not a marked feature Lastly he states that the presence of *Endamoeba histolytica* cysts in the feces does not always completely account for the whole clinical picture as is amply demonstrated in this address

He made a number of other interesting observations pertinent to the *question of the practice of medicine in the temperate zone* and he took up the question of tropical nontropical disease differentiation

Relative to tropical sprue he reported a number of cases referred to him as *gastric carcinoma duodenal ulcer cholecystitis* Addison's disease and pernicious anemia *all of* which were affected with tropical sprue

Sprue may be mistaken for Addison s disease for cholecystitis and for malignant diseases *Tropical ulcer is infrequent* in Europeans and when seen must not be mistaken for anything else He calls attention to the occurrence every now and then of cases of leprosy which may be extremely chronic in its *course and may have a latent period of over thirty years* before the lesions become obvious He warns of the necessity of diagnosis of helminthic infections which are usually symptomless and require *concentration methods of the feces for demonstration* of the eggs A most interesting case of *Clonorchis sinensis* infection was recorded in a Chinese politician with a long history of cholecystitis with fever pain and *jaundice* *Cholecystograms* revealed pigmented stones In addition he was a confirmed diabetic and operation was refused point blank As Sir Philip Manson Bahr put it *"Eventually he became the* Japanese puppet *at* Nanking so that in retaining his gall bladder he lost his

head!' Infections with *Loa loa* with Calabar swellings have been seen by Manson Bahr in London in a case originating in the tropics

His address from which I have quoted is a chronicle of the ups and downs of consulting practice in tropical medicine in London One must remember that the same thing might occur in New York Chicago St Louis or San Francisco Thus one must not confuse tropical medicine with temperate zone medicine and vice versa An even keel an understanding of clinical medicine in its entirety, is always necessary

TABLE I ROUTINE IMMUNIZATIONS

(From Technical Bulletin 114 by permission of the Department of the Army)

AGENT	NUMBER OF DOSES	INITIAL SERIES		STIMULATING DOSE	
		INDIVIDUAL DOSE	INTERVAL BETWEEN DOSES	WHEN INDICATED	AMOUNT
Smallpox vaccine	1	Contents of one capillary tube		Every 3 years with in 1 year prior to departure for over seas areas and in presence of the disease*	Contents of one capillary tube
Typhoid paratyphoid vaccine	3	First dose 0 5 c c second dose 1 0 c c third dose 1 0 c c	7 to 28 days	Annually and in the presence of the disease	One dose 0 5 c c
Tetanus toxoid (plain)	3	Each dose 1 0 c c	Minimum of 21 days	One year after initial series and upon occurrence of wounds or burns as directed by the medical officer	1 0 c c as booster dose

*f ditor a ... are actually occurring and ... the time of the last vaccir ... ination has not been caret ... vaccinati n, if within a p ... or a well defined accele ... he previous reaction was ... to ensure against the p ...

In concluding this chapter as an introduction to this subject as handled by our distinguished staff of authors I should like to call attention to a few generalities so well set forth in a pamphlet entitled *Health Hints for the Tropics* by Strode et al In it are discussed climate water food insects and insect vectors of disease immunization and miscellaneous hints The pamphlet contains much of value The authors warn tourists to take a middle ground when visiting the tropics one between the glamorous attitude and that of looking upon visiting Africa as visiting the white man s grave It is recommended that simple rules of health be followed care exercised in the choice of food and drink and physical defects removed before going to the tropics One must readjust himself to heat light and humidity and must remember above all that moderation in all things is the keystone of successful living in the tropics He should be especially careful about the water he drinks about the water he bathes in and the water used for laundering Wading swimming or bathing in places

where schistosomes are present, such as fresh water streams, lakes, marshes rice paddies, must be avoided. *Food contamination* must be looked for and avoided. Canned food offers a safety material for nutrition. Food handlers must be inspected. The vectors of disease notably, mosquitoes which transmit malaria and those which carry dengue fever, yellow fever, and filariasis, must be considered very seriously. One must remember that sandflies, fleas, ticks, mites, lice, tsetse flies and the reduviid or "kissing bug" may carry tropical diseases.

TABLE II. IMMUNIZATIONS REQUIRED FOR TRAVEL TO CERTAIN OVERSEAS AREAS (IN ADDITION TO ROUTINE IMMUNIZATIONS)

(From Technical Bulletin 114 by Permission of the Department of the Army)

AGENT	NUMBER OF DOSES	INITIAL SERIES: INDIVIDUAL DOSES	INITIAL SERIES: INTERVAL BETWEEN DOSES	STIMULATING DOSE: WHEN INDICATED	STIMULATING DOSE: AMOUNT
Typhus vaccine	2	1.0 cc each	1 week	At 4- to 6-month intervals in presence of danger of epidemic (louse-borne) typhus	1.0 cc
Cholera vaccine	2	First dose, 0.5 cc; second dose 1.0 cc	1 week	At 4- to 6-month intervals in presence of danger of cholera	1.0 cc
Yellow fever vaccine	1	0.5 cc of the proper dilution		Every 4 years, if in yellow fever endemic area	0.5 cc of the proper dilution
[illegible]	[illegible]	[illegible] cc	[illegible]	[illegible] ho ... of [illegible] plague	1.0 cc in ... ses ... ry

*Indicated in the presence of known cases.

TABLE III. DOSAGE OF IMMUNIZING AGENTS AND AGE OF ADMINISTRATION, FOR CHILDREN TRAVELING OUTSIDE THE UNITED STATES WHEN INDICATED FOR AREA OF DESTINATION

(From Technical Bulletin 114 by Permission of the Department of the Army)

IMMUNIZING AGENT	DOSAGE	AGE LIMIT
Smallpox vaccine	As for adults	All children regardless of age
Typhoid paratyphoid vaccine	Usual number and interval between inoculations; volume of each dose reduced according to weight (e.g., one-half adult dose for a child weighing 50 pounds)	Children over 1 year of age
Typhus vaccine	Usual number and interval, dosage reduced according to weight	Children over 1 year of age
Cholera vaccine	Usual number and interval, dosage reduced according to weight	Children over 3 months of age
Yellow fever vaccine	Usual full dose	Children over 3 months of age
Diphtheria toxoid	Usual full dose (either alum precipitated or fluid toxoid may be used, alone or in combination with other agents such as tetanus toxoid or pertussis vaccine)	All children between 3 months and 15 years of age

Spiders must not be overlooked or disdained

In this pamphlet are given three tables relative to immunization which are reproduced here for the information of those about to proceed to the tropics

One must especially look out for skin diseases in the tropics The skin must be especially cared for daily baths with thorough drying of the skin in the arm pits crotch beneath the breasts and between the toes

In the tropics one must be food conscious heat conscious and insect conscious

CHAPTER 2

A GENERAL CONSIDERATION OF THE PROTOZOA

ENRIQUE BELTRÁN

HISTORY

Because of the small size of these organisms protozoa were not seen by man until he learned to use magnifying lenses Anthony van Leeuwenhoek is generally credited with the discovery of protozoa and is justly regarded as the "father of protozoology"

After Leeuwenhoek's work, the study of protozoology advanced rapidly, especially with regard to free living organisms *Parasitic protozoa, however, did not at first excite great interest, although various isolated observations of these forms were made* It may be said that *medical and veterinary protozoology did not emerge as a branch of science until the end of the nineteenth century* Among many important contributions to this field may be mentioned the discovery of *Endamoeba gingivalis* by Gros in 1849, the first reported ameba of man, of *Endamoeba coli*, by Lewis in 1870 of *Endamoeba histolytica* by Lösch in 1875 in Russia Lewis, in 1878 observed the first *trypanosome in a mammal, in the blood of a rat* It must not be forgotten that *the first pathogenic microorganism studied by Pasteur was a protozoan (Nosema bombycis)* the cause of pebrine in silkworms

These observations did not [illegible] interest in the subject until the discovery by Laveran in 1880, in Algeria of [illegible] as well as the confirmation of knowledge with [illegible] finitely laid the basis for medical protozoology, this came a [illegible] present century, the work of Schaudinn playing a brilliant part

GENERAL CHARACTERISTICS OF PROTOZOA

Protozoa are usually microscopic organisms They are single cell organisms (Fig 1) This permits their differentiation from metazoa, or higher forms which are composed of more than one cell

Some protozoa are so small that they scarcely attain a size of one micron, as for example Leishmania or Babesia others as Nyctotherus or Opalina may *be several hundred microns* Some free living protozoa, such as *Spirostomum ambiguum*, may be as *large* as *2,000 microns* and are visible to the naked eye

The shapes of *the* protozoa vary *greatly* spherical (Halteria), oval (Holophrya) *changing forms* (*Amoeba*), *bell* shaped (*Vorticella*), *etc*

Some lack firmness of body to such extent that they continually undergo changes in shape, others show more resistance, either because their cytoplasm is firmer or because they are enveloped in a rigid membrane Occasionally especially *among* the free swimming forms they develop true shells or carapaces composed of various substances (*chitin*, calcium, and silicon salts, etc)

All protozoa have a more or less thin membrane which envelops the body In some (Infusoria) it is thick enough to be easily seen In others (Mastigophora and certain Sporozoa) it is thinner In some (Sarcodina) it is so thin that it is very difficult to observe For *this* reason, it was formerly thought th there were some protozoa *not* provided with a membrane, *these* were term

"naked" With the more modern methods of microdissection the existence of a membrane however thin it might be has been definitely proved in animals which once were thought to lack such a membrane A membrane no matter how thin plays a most important triple role retention protection and osmosis

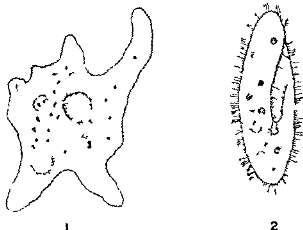

Fig 1.—Diagrammatic representation of an ameba 1, and a paramecium, 2 showing the unicellular character of protozoa (Original drawing of T … de Beltrán.)

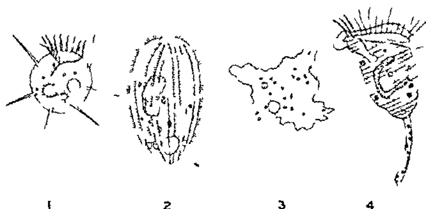

Fig 2.—Diagrammatic representation of various forms of protozoa 1 Halteria 2 Holophrya 3 Ameba 4 Vorticella (Original drawing of T G de Beltrán.)

As in every cell the cytoplasm is composed of a gelatinous and semifluid mass which can usually be differentiated into two parts an outer layer, slightly granular and relatively firm called the *ectoplasm*, and the central mass more fluid and granular which is the *endoplasm* In addition to vacuoles the cytoplasm in a great majority of protozoa also contains nutritional reserves metabolic products mitochondria Golgi apparatus, and other structures that are seen in the cytoplasm of the cells of metazoa

The nucleus is situated in the endoplasm Fundamentally it may be either (1) *vesicular*, when it presents an enveloping membrane filled with

nuclear fluid in which chromatin granules are observed, and generally a corpuscle more or less central called *karyosome (endosome)*, or (2) *compact*, with the chromatin granules so compressed one against the other that only a uniform mass is seen within the membrane In certain protozoa one does not see nuclei of one of the types mentioned but only a series of chromatin granules perhaps combined with other substances scattered throughout the cytoplasm, in such cases we speak of a *diffuse nucleus* In Infusoria we observe a peculiar double or dimorphous type of nuclear apparatus, made up of two distinct elements called *macronucleus* and *micronucleus* respectively

Some protozoa pass the greater part of their lives in a sedentary position because they are devoid of means of motility The majority, however, are endowed with active locomotion that may be carried on by means of *pseudopodia*, which are variable and transitory expansions of the body, *flagella*, which are vibratory appendages whip like long but not numerous, and *cilia* which are also vibratory appendages smaller and more numerous than flagella

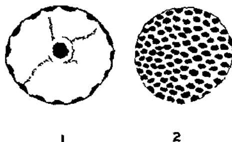

Fig 3 —Types of nuclei of protozoa (schematic) 1 vesicular 2 compact. (Original drawings of T G de Beltrán)

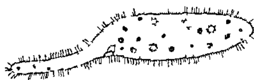

Fig 4 —Diagrammatic representation of *Dileptus anser*, showing the diffuse type of nucleus (Original drawing of T G de Beltrán)

The large majority of free-living protozoa and a number of the parasitic protozoa derive their nourishment by ingesting animal or vegetable particles this form of nutrition is called **holozoic** Other protozoa derive their food from organic substances which have been dissolved and partially processed, these substances are absorbed through the membrane Last there is a group of chlorophyll bearing flagellates which are able to synthesize organic material from inorganic after the manner of plants this method of nutrition is the **holophytic** type This last curious group is difficult to interpret so that botanists and zoologists are in dispute about them some considering them to be plants others classifying them as animals

Reproduction may be by division of the individual to form two entities of similar size **binary fission**, or by division of the individual into several entities

of similar size, **multiple fission**; or the animal may separate a small part of its body to form a new individual, **budding**

In the process of multiplication, the nucleus begins to divide into two or more portions and next the cytoplasm divides Division of the nucleus in protozoa was formerly described as amitotic It has been observed, however, that protozoa present forms of mitosis that are more or less similar to those observed in the cells of metazoa Moreover, in many protozoa, we observe sexual phenomena that are sometimes very complex

The protozoan life cycle frequently presents vegetative forms, which carry on all the functions necessary to life, and cystic forms, which permit the organism to resist adverse environmental conditions under protection of the cyst wall Occasionally the cyst may also be a form of reproduction, the organisms multiplying within the cyst

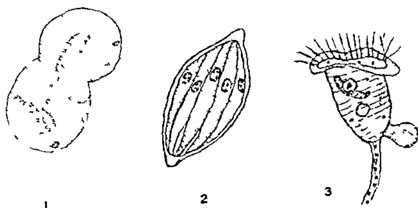

Fig 5—Diagrammatic representation of the different types of cellular reproduction of protozoa *1* binary fission (Nyctotherus) *2*, multiple fission (Monocystis) *3*, budding (Vorticella) (Original drawing of T G de Beltrán)

Some parasitic protozoa pass their entire life within the host, from which they may be directly transmitted to another (*Endamoeba gingivalis* or *Trypanosoma equiperdum*), some live within the host and leave in the form of cysts, in which form they infect new persons or animals (*Endamoeba histolytica* or *Giardia lamblia*), last, there are some which must pass successive stages of their existence in different hosts (*Plasmodium vivax* or *Trypanosoma gambiense*)

CLASSIFICATION

Protozoa are classified as follows

Class Mastigophora Provided with flagella as organs of locomotion, vesicular nucleus most often reproduction by longitudinal binary fission Free living and parasitic

Class Sarcodina Provided with pseudopodia as organs of locomotion, vesicular nucleus division by binary fission, multiple fission, or budding, sometimes with elaborate shells or carapaces Free-living and parasitic

Class Infusoria Provided with cilia as organs of locomotion at least during certain phases of their existence, dimorphic nuclear apparatus, the nuclei of which may be vesicular or compact, *exhibiting in the life cycle a special sexual phenomenon termed conjugation* Free living or parasitic

Class Sporozoa Devoid of special organs of locomotion and consequently having stationary habits, with rare exceptions, reproduction by multiple fission life cycle complicated, sometimes in different successive hosts Exclusively parasitic

ECOLOGY

Protozoa, with rare exceptions, may present two forms *trophozoites*, which move and obtain their nourishment actively, and *cystic forms*, which are surrounded by a protective envelope and can thus withstand adverse conditions

Trophozoites require a high degree of humidity in order to subsist Most of them require a liquid medium, or at least sufficient moisture Drying, even though not extreme, causes death of any protozoan in its vegetative form

Cysts, within which the organism maintains a latent existence (with the exception of the phenomena of multiplication which occasionally may be observed in this phase), have a markedly greater resistance to external destructive elements and particularly to drying because of their enveloping cover Cysts of protozoan parasites of man are sensitive to drying although they are more resistant than the trophozoites

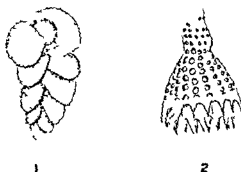

Fig 6.—Types of shells formed by protozoa 1, calcareous shell of a foraminifer 2, siliceous shell of a radiolar (Original drawing of T G de Beltrán)

Many forms of protozoa easily accommodate themselves to changes in the medium in which they live However, in each particular medium there is observed a predominance of certain species and a habitual association with other species, so that one may speak of *ecologic centers* Calkins (1933) has enumerated the six chief forms according to adaptations to specific media aquatic, semiterrestrial, terrestrial, sapropelic, coprozoic, and parasitic forms

From the medical standpoint the last two forms are most important The cysts of **coprozoic forms** can pass without modification through the digestive tract of man and animals passing from the body of the host in the excreta in which, environmental conditions being favorable, further development into the trophozoite from may take place These forms may be confused with parasitic forms whereas they are merely incidental elements in transit through the digestive tract

Parasitic forms are those which habitually live upon or within other organisms and which can present many stages in their adaptation to parasitic existence. Less thoroughly adapted forms are those of ectoparasites, as for example, *Hydramoeba hydroxena*, which lives on the ectodermal cells of the hydra. *Ichthyophthirius multifilus*, an infusorian parasite of fish, is sometimes a true ectoparasite on the skin of the fish, while at other times it is beneath the skin where it forms abscesses; it could be considered as an intermediate between ectoparasites and endoparasites.

Endoparasites also may exist in various stages. Sometimes the parasite lives simply in the cavities of the host when it is termed *coelozoic*, such as *Endamoeba coli* in man. Others, as *Endamoeba histolytica*, penetrate into the tissues and are called *histozoic*. Finally some not only enter the tissue, but localize within the cells themselves, as *Leishmania braziliensis*, in which case the parasitic form is termed *cytozoic*.

BIOLOGIC AND ECONOMIC IMPORTANCE

Protozoa breeding in fresh or salt water frequently constitute the principal food for larger animals. Thus directly or in their role as food for other larger forms they may be of definite economic importance.

As protozoa in the ocean provided with shells die, their shells drop to the bottom as sedimentary formations and through geological changes produce chalk, infusorial earth, silica sand, etc. Various industrial uses, filters, polishing powders, etc., give them economic value.

In humid soil there are masses of protozoa, principally sarcodines and mastigophores, the biological significance of which is not definitely known, but which in their association with bacteria living in the same medium certainly play an important part in the agricultural characteristics of the soil.

But if the foregoing aspects of these forms are important, their significance in relation to man is still more important if we consider them in their association with other living organisms.

In the ensuing chapters will be found detailed information concerning the principal protozoa that are parasitic to man, as well as the diseases which they cause and the most adequate means of prevention and cure.

CHAPTER 3

INTESTINAL PROTOZOA OF MAN

ENRIQUE BELTRÁN

In the digestive tract of man there can be found various protozoa Some cause disturbances, while others appear to be purely commensal, with no pathogenic significance

Protozoan parasitism of the human intestine presents many very interesting problems For more detailed information, the reader is referred to Dobell and O'Connor (1921), Hegner (1927), Lynch (1930), Gradwohl and Kouri (1948), and Beltran (1948), or for particular problems to Dobell (1919) and Craig (1911, 1934, 1944), etc

We shall discuss the intestinal protozoa of man by treating separately the members of each of the four protozoan classes

SARCODINA

Sarcodina are characterized by *locomotion through transitory and variable extensions of the body* called *pseudopodia*

The group is *very extensive and includes many free living forms*

One of the five orders into which the class is divided is the order Amoebida, characterized by lack of shells and by formation of pseudopodia which are wide and variable, called *lobopodia* *Amoeba proteus is one of the better known representatives of this order*

Sarcodina which inhabit the human intestine are generally designated as *intestinal amebae* and are closely related to *Amoeba proteus* None belong to the genus Amoeba but to other genera

Parasitic amebae of man are small forms which do not exceed some 50 microns for the largest, with two exceptions, they may be found *in the trophozoite as well as in the cystic form*

These parasites are, at the present time, considered as belonging to six different species distributed into four genera Endamoeba, Endolimax, Iodamoeba, and Dientamoeba The principal characteristic for differentiation is the nucleus

The nucleus of all intestinal amebae is, as in all the Sarcodina, of the vesicular type In the genus Endamoeba the nucleus displays peripheral chromatin granules that are more or less regular, according to the species From this peripheral chromatin, fine granular filaments radiate toward a central *or excentric karyosome (endosome), usually with a rounded appearance* *In properly stained specimens*, one can distinguish one or more central granules deeply staining embedded in a matrix with less chromatic affinity The genus Endolimax is generally described as having a nucleus which lacks the peripheral chromatin However, some authors (Stabler, 1932) mention the presence of chromatin granules which are adherent to the membrane and *which may be observed under certain conditions* Within *the nucleus is a karyosome* (endosome), generally of irregular form, large, *and adjacent or adherent* to the outer wall of the nucleus In the genus Iodamoeba

the peripheral chromatin is absent and the large, spherical karyosome is centrally located. Under usual conditions of observation, this karyosome is seen as a uniform mass, but in very good preparations there can be seen a central mass, deeply stained, surrounded by a series of small granulations with weaker affinity for dyes, described by some authors as "pearls" The genus Dientamoeba has a nucleus without peripheral chromatin and with a karyosome formed of various large and irregular granules, deeply stained, generally situated in the center, and embedded in a matrix with poor staining qualities, frequently irregular in form, the name of the genus (Greek *di*, two) alludes to the fact that two nuclei are found in many of the trophozoites

Sarcodina which inhabit the human digestive tract are ***Endamoeba histolytica*** (Schaudinn, 1903), ***Endamoeba coli*** (Grassi, 1879), ***Endamoeba gingivalis*** (Gros, 1849), ***Endolimax nana*** (Wenyon and O Connor, 1917), ***Iodamoeba williamsi*** (Prowazek, 1911), ***Dientamoeba fragilis*** (Jepps and Dobell, 1918)

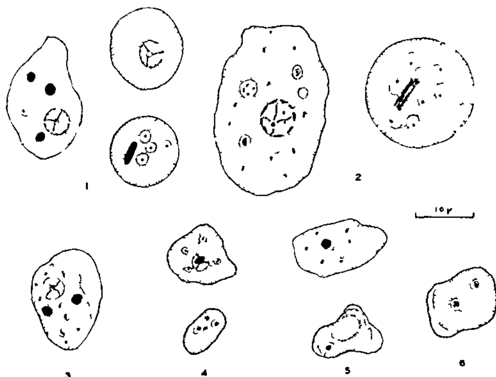

Fig 7—Parasitic amebae of man schematic representation 1 *Endamoeba histolytica* (trophozoite precyst and cyst) 2, *Endamoeba coli* (trophozoite and cyst) 3 *Endamoeba gingivalis* 4 *Endolimax nana* (trophozoite and cyst) 5 *Iodamoeba williamsi* (trophozoite and cyst) 6 *Dientamoeba fragilis* (Original drawing by T G de Beltrán)

Although the six species listed here are considered correct without exception some authors accept the existence of further species, the most frequently cited being ***Entamoeba hartmanni*** Prowazek, 1912, ***Entamoeba minuta*** Elmassian 1909 ***Entamoeba tetragena*** Viereck 1907 ***Entamoeba dispar*** Brumpt, 1925, ***Councilmania lafleuri*** Kofoid and Swezy, 1921 ***Karyamoeba falcata*** Kofoid and Swezy 1924 but these seem to be simply synonyms of the generally accepted species

There is also another noteworthy discrepancy with respect to the correct designation of species, the discussion centering principally upon the justification for using the generic name Endamoeba Leidy, 1879, or Entamoeba Cassagrandi and Barbagallo, 1895, and for using the species name *histolytica* Schaudinn, 1903, or *dysenteriae* Councilman and Lafleur, 1891 Another controversial point is whether the species designation *williamsi* or *butschlii* is to be preferred for amebae of the genus Iodamoeba

Endamoeba Histolytica (Schaudinn, 1903)

E histolytica is a protozoan which varies in size from 10 to 30 microns, most commonly occurring in the lower range The trophozoite moves actively, constantly changing shape In fresh and vigorous specimens the body is frequently elongated, with but one large pseudopodium projecting in the direction of movement A similar shape may also be observed in organisms in permanent mounts In the usual preparations, however, the rounded forms predominate, if the sample has stood for some time after collection before being examined.

One of the most noticeable morphologic characteristics of these protozoa, when they are alive, is the ease with which the ectoplasm can be distinguished from the endoplasm The ectoplasm is hyaline and transparent, while the endoplasm is translucent and more granular In the endoplasm can be seen vacuoles which may contain ingested red blood cells, although many do not show these corpuscles There is no food material within the endoplasm In degenerated specimens, vacuoles containing bacteria and other extraneous particles can be seen This also occurs in cultures, in which also starch granules are ingested

The nucleus is spherical, vesicular in type, with a series of small peripheral, refractile, quite regular lines of granules There is a very refractile central karyosome In preparations stained with hematoxylin, the peripheral chromatin granules are regular in shape and of uniform size, between the granules and the small central karyosome there is a series of small radiations of chromatin granules of variable staining intensity

The so called precystic forms are round and devoid of pseudopodia or nutritional inclusions A cyst wall is lacking

Cysts, usually spherical or spheroidal, are of variable size, measuring from 5 to 20 microns, averaging 10 microns It is thought that the cysts tend to be of uniform size within a certain race and that consequently there are different races of this species which differ from each other in the size of the cysts

The nucleus of the cyst has the same appearance as that of the trophozoite In newly formed cysts, only one nucleus is seen After division, this nucleus forms two, and by the second division, four nuclei This number is characteristic of mature cysts and predominates in specimens obtained from fecal matter

Bar like bodies, called chromatoid bodies, are frequently observed, they have rounded ends and appear very refractile in fresh specimens In preparations stained with iron hematoxylin, they are intensely black

Physiology—*E histolytica* is exclusively parasitic It must live within the body tissues of man or animals The trophozoites can survive for only a short period of time outside the body of the host The cysts have greater resistance

Like all parasites which inhabit the intestines, *E. histolytica* has become adapted to living in media poor in oxygen, but the organism is not a strict anaerobe since it can apparently be cultivated under aerobic conditions

Life Cycle—Mature or quadrinucleate cysts constitute the infective forms They enter the human organism by way of the mouth, passing undamaged through the stomach, thence to the small intestine Here the cyst wall softens and breaks, due to the action of digestive ferments, and a quadrinucleate ameba is released The quadrinucleate ameba

undergoes two cytoplasmic divisions without further nuclear division giving rise to four active amebae. Occasionally nuclear division may also take place; this results in the production of eight very small amebae (Faust 1943).

The metacystic amebae migrate into the large intestine and establish themselves in the walls, especially in the ileocecal region and in the first part of the ascending colon, as well as in the rectosigmoid. At these sites at autopsy there is seen a predominance of lesions caused by *E. histolytica*. The infection is very persistent, according to Dobell and Stevenson (1918); *it may last throughout the life of the host*.

While in the intestinal mucosa the amebae multiply repeatedly by binary fission (Dobell 1919). For reasons as yet unexplained some of the entamebae which remain in the intestine expel their nutritional material, undergo reduction in size, possibly by division, and become rounded, constituting the so-called *precystic forms*. These precystic *forms are later enveloped by a resistant membrane forming the uninucleate cysts*. When they mature they are transformed into the quadrinucleate infective forms. These forms, if ingested by the *proper host, begin again the life cycle just described*.

Although the habitual site of *E. histolytica* is the large intestine, at times the parasites are carried to other organs, where they produce suppurative abscesses.

Culture.—*E. histolytica* is easily cultivated on various media, the most commonly used being those of Boeck and Drbohlav (1925), Locke egg serum or Locke egg albumin, Craig, St. John serum media, Tsuchiya (1934), and Balamuth.

Inoculation of Animals.—Lösch, who discovered *E. histolytica*, successfully reproduced *the infection in dogs, and this method, though little favor, has come into usage again*, especially by Faust (1930). Kittens were used for the first time by Hlava in 1887; they are considered excellent laboratory animals for this purpose and are now used extensively. Jones (1946) introduced the use of rats in such experiments.

Endamoeba Coli (Grassi 1879)

E. coli is somewhat similar to *E. histolytica*. It is usually described as being larger, varying from 10 to 40 microns.

The ectoplasm is much less hyaline and less transparent than that of *E. histolytica* and is not well differentiated *from the endoplasm. In the endoplasm there are a large number of* vacuoles containing a variety of nutritional materials—bacteria, yeasts, *cysts of other* protozoa, etc. The pseudopodia are similar in shape to those of *E. histolytica* but frequently are blunt and are not projected in any definite direction.

The nucleus is characterized by peripheral chromatin granules, coarser and more irregular than those of *E. histolytica*. They are more readily distinguishable due to their refractile character. The karyosome, which is larger and less refractile, is excentrically located.

Precystic *forms*, which measure about 15 microns, are similar to those of *E. histolytica*, from which they can be differentiated by nuclear characteristics.

The **cysts** are spherical or spheroidal, seldom irregular, and vary from 10 to 30 microns. The membrane which surrounds them presents a well-marked double contour. They are *originally uninucleate, though soon they become binucleate, then four and eight nuclei, the* last number considered typical of mature cysts. They contain a large amount of glycogen, which accounts for their dark brown color with iodine solution. They frequently lack chromatoid bodies; when present they are needle-shaped and sometimes joined together, forming larger or smaller clusters.

Life Cycle.—The life cycle is similar to that of *E. histolytica*, with the difference that this ameba, once established in the large intestine, lives within the lumen and feeds on bacteria and other material without invading the tissue. For this reason it is considered a simple commensal.

The incidence is high. It has been calculated that about 50 per cent of the entire population of the world harbors *E. coli*. The mechanism of transmission is presumably the same as that for *E. histolytica*.

This species is difficult to cultivate. The parasite is not easily transmitted to animals.

There is also another noteworthy discrepancy with respect to the correct designation of species, the discussion centering principally upon the justification for using the generic name Endamoeba Leidy, 1879, or Entamoeba Cassagrandi and Barbagallo, 1895, and for using the species name *histolytica* Schaudinn, 1903, or *dysenteriae* Councilman and Lafleur, 1891 Another controversial point is whether the species designation *williamsi* or *bütschlii* is to be preferred for amebae of the genus Iodamoeba

Endamoeba Histolytica (Schaudinn, 1903)

E. histolytica is a protozoan which varies in size from 10 to 30 microns, most commonly occurring in the lower range The trophozoite moves actively, constantly changing shape. In fresh and vigorous specimens the body is frequently elongated, with but one large pseudopodium projecting in the direction of movement A similar shape may also be observed in organisms in permanent mounts In the usual preparations however, the rounded forms predominate, if the sample has stood for some time after collection before being examined

One of the most noticeable morphologic characteristics of these protozoa, when they are alive, is the ease with which the ectoplasm can be distinguished from the endoplasm. The ectoplasm is hyaline and transparent, while the endoplasm is translucent and more granular In the endoplasm can be seen vacuoles which may contain ingested red blood cells, although many do not show these corpuscles There is no food material within the endoplasm In degenerated specimens, vacuoles containing bacteria and other extraneous particles can be seen. This also occurs in cultures, in which also starch granules are ingested

The nucleus is spherical vesicular in type, with a series of small peripheral, refractile, quite regular lines of granules There is a very refractile central karyosome In preparations stained with hematoxylin, the peripheral chromatin granules are regular in shape and of uniform size, between the granules and the small central karyosome there is a series of small radiations of chromatin granules of variable staining intensity

The so called **precystic forms** are round and devoid of pseudopodia or nutritional inclusions A cyst wall is lacking

Cysts, usually spherical or spheroidal, are of variable size, measuring from 5 to 20 microns, averaging 10 microns. It is thought that the cysts tend to be of uniform size within a certain race and that consequently there are different races of this species which differ from each other in the size of the cysts

The **nucleus of the cyst** has the same appearance as that of the trophozoite In newly formed cysts, only one nucleus is seen After division, this nucleus forms two, and by the second division, four nuclei This number is characteristic of mature cysts and predominates in specimens obtained from fecal matter

Bar like bodies called **chromatoid bodies,** are frequently observed, they have rounded ends and appear very refractile in fresh specimens In preparations stained with iron hematoxylin, they are intensely black

Physiology—*E histolytica* is exclusively parasitic It must live within the body tissues of man or animals The trophozoites can survive for only a short period of time outside the body of the host The cysts have greater resistance

Like all parasites which inhabit the intestines, *E. histolytica* has become adapted to living in media poor in oxygen, but the organism is not a strict anaerobe since it can apparently be cultivated under aerobic conditions

Life Cycle—Mature or quadrinucleate cysts constitute the infective forms They enter the human organism by way of the mouth, passing undamaged through the stomach, thence to the small intestine Here the cyst wall softens and breaks, due to the action of digestive ferments, and a quadrinucleate ameba is released The quadrinucleate ameba

undergoes t o cytoplasm d v sions without further nu lear d v s on g v ng rise to four active amebae Occas onally nuclear d v s on may al o take place th s results in the pro du t on of e gl t very small amebae (Faust 1943)

The meta ystic amebae m grate into the large inte t ne an l establ sl themselves in the walls espec ally in the ileocecal reg on an l in the first part of the as en l ng colon as well as in the rectos gmo d At these s tes at autopsy there is seen a pre lom nance of les ons caused by *E histolyt ca* The infect on s very pers tent ac or l ng to Dobell and Stevenson (1918) it may last throughout the l fe of the host

Wl le in the intest nal mucosa the amebae mult ply repeatedly l y b nary fi s on (Dobell 1919) For reasons as yet unexpla ned some of the e amebae wh ch rema n in the intest ne exp l the r nutr t onal mater al un l rgo re luct on n s ze poss bly l y l v on an l become roun led const tuting the so called *precyst c* forms These pr cyst c forms are later en v loped by a res stant membr ne form ng tl e un nu leate cysts When they mature they are transformed into the quadr nucleate nfect ve forms Tl e e forms if inge te l by the proper host begin aga n the l fe cycle just de cr bed

Although tl e l ab tual s te of *E h stolyt ca* is tl e large nte t ne at t n es the parasites are carr ed to other organs here tl ey produce sup purat ve abscesses

Culture—*E h stolyt ca* is eas ly cult vated on v r o s me l a the most commonly used be ng tl ose of Boeck an l Drbohlav (19 5) Locke egg serum or Locke egg alb im n Cra g St John serum me l a Tsuch ya (1934) and Balamuth

This spec es s d ff ult t cult vate The para te is not eas ly transm tted to an mals

Differentiation Between Endamoeba Histolytica and Endamoeba Coli

Since *E histolytica* and *E coli present major points of similarity, and since* it is important to identify *E histolytica* correctly, the most important characteristics generally used to differentiate these two amebae are given

The cysts and trophozoites of E histolytica are usually smaller than those of *E coli* Size alone however is not an absolute means of differentiation, since at times the sizes vary and cysts and trophozoites of *E histolytica* are rather large

One of the most important means of identification is the differentiation of the ectoplasm and the endoplasm and the nature of the amebic movements, this is of value, however, only in normal and vigorous living specimens

The contents of the food vacuoles is very important: *E histolytica habitually shows only ingested erythrocytes, or completely lacks food vacuoles,* whereas *E coli* shows very abundant *food* vacuoles containing a variety of material In *degenerated E histolytica* are seen vacuoles containing ingested *bacteria and there are some reported cases of E coli containing ingested erythrocytes* (Tyzzer and Geiman 1938)

Cysts help differentiate the two species the size, the nature of the membrane (single in *E histolytica,* double in *E coli*), and the nature of the chromatoid bodies Of greater importance is the structure of the nuclei which, as in the trophozoites offers a more certain identification in stained slides The number of nuclei is also a means of differentiation but *this is not always reliable It appears* (Beltran, 1945b) that even though the number of supernucleated cysts of *E coli* may be large up to 20 per cent this is of no particular importance in diagnosis, whereas the number of supernucleated cysts in *E histolytica,* which might cause serious confusion is barely 3 to 4 per cent

Fig 8—Trophozoite of *Endamoeba gingivalis* stained with iron hematoxylin The nucleus is seen in the central portion the remnants of ingested leucocytes in the food vacuoles (×3 000) (Original photomicrograph of E Beltrán)

Endamoeba Gingivalis (Gros, 1849)

E gingivalis, although not a true intestinal ameba, since it lives in the mouth, is mentioned here only because of its high incidence it occurs in about

50 per cent of adults Morphologically it resembles *E. histolytica* from which it differs in a few slight details of nuclear structure The food vacuoles contain a variety of materials, such as bacteria and other microorganisms and the remnants of leucocytes

This species has no cystic form in its life cycle It is assumed that transmission from person to person takes place by direct contact, especially through kissing

This species has aroused the interest of many authors Some (Bass and Johns, 1915, Smith and Barrett, 1915, etc) considered it to be of etiologic importance in pyorrhea alveolaris, although most contemporary authors do not accept this view In accordance with our own investigations (Beltrán and Molina 1944), we think that this subject still merits further serious consideration before it will be possible to arrive at a definite conclusion

Endolimax Nana (Wenyon and O'Connor 1917)

These are small amebae varying from 6 to 12 microns Differentiation between the ectoplasm and the endoplasm is variable while perfectly marked in some in others it is observed only with the greatest difficulty or not at all The endoplasm contains abundant food vacuoles containing a variety of material This fact in conjunction with the characteristics of their movements sluggish and in different directions sometimes causes this species to be confused with small *E. coli* The nucleus constitutes the most important diagnostic characteristic of the parasite

Cysts are ovoid less frequently spherical with four nuclei in the mature state The nuclei have the same characteristics as those found in the trophozoite, but they are barely visible in fresh specimens

They measure approximately 8 to 10 microns along the longer axis Young stages frequently show glycogen distributed diffusely or concentrated in vacuoles which sometimes resemble those found in Iodamoeba

Dobell (1919) described the occasional presence of filaments which stain black with iron hematoxylin

The life cycle of this species appears to be similar to that of *E. coli* being a simple commensal of the human intestine

Incidence is about 10 per cent In our investigations in Mexico we found an incidence between 8 and 32 per cent

Iodamoeba Williamsi (Prowazek 1911)

These are small organisms varying from 5 to 20 microns The ectoplasm is not clearly differentiated from the endoplasm The endoplasm contains numerous nutritional vacuoles with the most varied contents Movement of the ameba is sluggish frequently not directional

The nucleus which is practically invisible in fresh specimens is the principal distinctive characteristic of these amebae in stained preparations

Cysts are most frequently uninucleate The nucleus is practically invisible in fresh specimens and barely detectable in preparations treated with iodine The most notable characteristic is the great irregularity of outline Another very characteristic structure is the glycogen vacuole with its definitely limited outline which occupies a large part of the cyst In fresh specimens or in specimens stained with hematoxylin it appears as a clear space while in specimens stained with iodine it appears as a well defined mahogany-colored mass

It has often been stated in the literature that the cysts are found in large numbers in infections due to this species but that only rarely are the trophozoite forms found. It has

been my experience (Beltrán, 1945a) that this is not necessarily the case, since the vegetative forms, sufficiently abundant in liquid feces, also are found in appreciable numbers in formed stools.

The life cycle is similar to that of the species just described, and it is also considered as harmless to man. It occurs quite frequently, our studies showing an incidence of 7 to 31 per cent.

Dientamoeba Fragilis (Jepps and Dobell, 1918)

These parasites are easily destroyed, for which reason the name *fragilis* has been given to the species. They are small, from 4 to 12 microns. The ectoplasm and endoplasm are clearly differentiated. They project hyaline, transparent pseudopodia which resemble those of *E. histolytica*, although they are not formed with the same rapidity. The nucleus is the most outstanding characteristic. There are often two nuclei.

The life cycle differs from other parasitic amebae of man, with the exception of *E. gingivalis*, in that no cysts are known. Because of this, details of the transmission are still obscure.

Reports of the incidence of this parasite vary. Most authors agree that it is the least frequent of the amebae of man. In our own epidemiologic surveys (Beltrán and Larenas, 1941), we have found an incidence as high as 9 per cent.

Although the majority of authors believe that this organism is not pathogenic to man, there are several reports of clinical cases supposedly caused by this species. Recently Wenrich (1944) reviewed the literature on this point and insisted upon the possible pathogenicity of these organisms although he admits that data sufficient for absolute confirmation have not been brought forth.

MASTIGOPHORA

Members of this class are characterized by having, as organs of locomotion, long vibratory whip-like appendages, called flagella, from which is derived the name "flagellates," commonly applied to them.

Certain flagellates live in the blood and the tissues; these are called *hemoflagellates*. Another group lives in the intestine; these are called *intestinal flagellates*. Generally included in this group, although they are not, strictly speaking, intestinal inhabitants, are species found in the mouth and in the vagina.

Polymastigina, one of the four orders into which this class is divided, is characterized by three to eight flagella, with the exception of the family Polymonadinae, which has more. In some species, there is an undulating membrane. They have one or more nuclei of the vesicular type. Certain forms which feed upon solid particles have a cytostome for ingestion, while others lack such orifices and derive their nourishment by absorbing nutritive materials through the entire body surface. Some form both trophozoites and cysts, while others have no cystic stage. There are a great number of species of both free-living and parasitic forms.

Several species live in man. Most authors agree that the following are parasitic to man: *Trichomonas hominis* (Davaine, 1860), *Trichomonas tenax* (O. F. Muller, 1773), *Trichomonas vaginalis* Donné, 1837, *Giardia lamblia* Stiles, 1915, *Chilomastix mesnili* (Wenyon, 1910), *Enteromonas hominis* da Fonseca, 1915, *Retortamonas (Embadomonas) intestinalis* (Wenyon and O'Connor, 1917).

Other species have been described, unsupported by sufficient evidence, and not accepted by the majority of authors.

There is also a great discrepancy with regard to the nomenclature of these parasites

Genus Trichomonas

These are pear shaped organisms with rounded anterior end The body is *traversed throughout the long axis by an axostyle which projects from the* posterior end, *according to the species* The flagellar apparatus consists of free flagella at the anterior end with one flagellum extending *from front to* back to form the axoneme of the undulating membrane

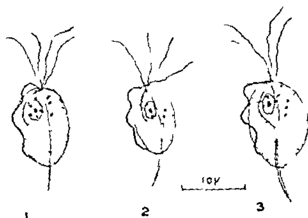

Fig 9—Comparative diagram of human parasites in the genus Trichomonas 1 *T hominis* 2 *T buccalis* 3 *T vaginalis* (Original drawing of T G de Beltrán.)

Trichomonas Hominis Davaine 1860

T hominis varies in length from [illegible] to 20 microns Each anterior flagellum originates from an independent basal corpuscle Close to this is the flagellum which forms the axoneme The axostyle is straight or slightly curved and extends beyond the posterior extremity The cytostome is small buttonhole in shape and is found near the anterior end Near the anterior extremity is the nucleus which is spherical or slightly ovoid, with a small karyosome, with a variable quantity *of* chromatin granules in the *nuclear* material In the anterior part of the body between the wall and the *nucleus* there is a group of small blepharoplasts, in longitudinal rows giving a "dotted" effect.

Old, degenerated organisms have an ameboid appearance with few structural details In such cases the most apparent characteristic is the undulating membrane, movements of which usually persist for a long time

The parasite moves rapidly by a series of small "jumps", the undulating membrane moves continuously This movement under low magnification appears merely to be a change in the shape of the body The anterior flagella also vibrate rapidly

They obtain their nourishment by ingesting various microorganisms Occasional ingestion of red blood cells has been observed (Hegner 1938)

Reproduction occurs by longitudinal binary fission There are no cysts the supposition being that transmission from subject to subject is accomplished through trophozoites which can pass through the stomach without damage

Some investigators consider Trichomonas nonpathogenic, others believe they can produce diarrhea and colitis Among those who take the latter view are Escomel (19[illegible]7) Kofoid and Swezy (1924) and Muro (1937)

Some authors relate the problem of pathogenicity to the number of flagella that is they consider that *only those with five flagella* (the genus Pentatrichomonas) are pathogenic

Incidence is variable In our investigations this parasite was found in 9 to 54 per cent

Culture of *T hominis* is successful in media similar to those used for *E histolytica* Rats can be easily infected with *T hominis* but the susceptibility of different strains of rats varies (Hegner and Eskridge, 1935)

Trichomonas Tenax (*Muller 1773*)

This flagellate is found in the human mouth in the tartar around the teeth *and in the cavities* of dental caries and in the pus of pyorrhea alveolaris (Gradwohl and Kouri 1948)

The morphology is similar to that of *T hominis* Whether or not they are the same species has been much discussed Wenrich (1931 1939) found certain morphologic differences which may be seen in Fig 9 Experiments by Bonestell (1936) and others confirm that we are dealing with distinct species

The *incidence of this parasite appears to be rather high* since Beatman (1933) found 22 7 per cent positive cases in 350 persons examined in Philadelphia It is supposed that transmission occurs in a manner similar to that of *E gingivalis*

Trichomonas Vaginalis Donné, 1837

This species shows great morphologic similarity to the preceding species, however *some differences which can be seen in Fig 9 may be observed*

It occurs in the vaginal mucus and reproduces by longitudinal binary fission Formation of cysts has not been observed Its nutritional requirements are still in dispute, some authors assume that it lives upon bacteria or that it ingests red blood cells (Andrews 1929) Others (Bland et al 1932) believe that leucocytes are ingested by Trichomonas and in turn that Trichomonas are ingested by leucocytes

Transmission is venereal as well as by contact with contaminated objects

Although the pathogenicity of this organism is still a matter for discussion most authors hold *it responsible for certain gynecologic conditions*

Incidence appears to be high in both sexes Andrews (1938) found an infection rate of 38 per cent Bland et al (1932) of 17 8 per cent in women Deo (1944) found 15 5 per cent of males infected He believes that the male is the transmitter and the female the reservoir

Cultivation of *these organisms is successful in many media* containing physiologic saline and protein material

Giardia Lamblia Stiles 1915

The body the major axis *of which is approximately* 10 to 20 microns is pear shaped with the wider part at the anterior end tapering to a point toward the posterior end From the posterior extremity project two tail like flagella *If viewed from the side the organisms*

have a concave structure, like a sucker, at the anterior extremity this is the *cytostome* and serves to attach the parasite to the wall of the small intestine, producing irritation of the intestine

The organism is seen in Fig 10, with a large cytostomal area, peristomal fiber surrounding the two nuclei, forming a sort of bowknot, and a series of blepharoplasts from which flagella arise The latter are two anterior, two lateral two ventral and two caudal Toward the center of the body are two wedge like parabasal bodies

The cysts are ovoid, from 10 to 15 microns along the greater axis, with thick, resistant walls The shape of these cysts is very characteristic Within the cysts, two to four anterior nuclei and remnants of the fibers which form the axostyle are seen Frequently the parabasal bodies are observed

In fresh stools these organisms may be seen moving rapidly, with their flagella, which are more readily visible than those of other species

Infection occurs by ingestion of cysts which pass through the stomach and reach the small intestine

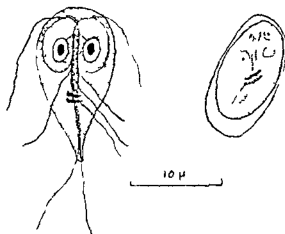

Fig 10—Diagrammatic representation of *Giardia lamblia* At the left is a trophozoite at the right, a cyst (Original drawing by T G de Beltrán)

Some authors deny a pathogenic role others insist upon it There are reasons for assuming that it is pathogenic

This parasite is cosmopolitan although more common in high temperate regions We have found an incidence of 6 to 34 per cent

Chilomastix Mesnili (Wenyon 1910)

This organism measures 10 to 20 microns along its longer axis It also is pear shaped but is not bilaterally symmetrical

The posterior half of the body is often twisted It has a single nucleus relatively large and vesicular near the anterior extremity Near the nucleus there is a group of blepharoplasts from which arise three free anterior flagella Another flagellum with the same origin passes within the organism inside the cytostome the sides of which are supported by two small lateral fibrils

The cysts are lemon shaped 6 to 9 microns long The nucleus as well as remnants of the neuromotor apparatus especially the flagellum within the cytostome can be seen

Some authors relate the problem of pathogenicity to the number of flagella that is they consider that only those with five flagella (the genus Pentatrichomonas) are pathogenic

Incidence is variable In our investigations this parasite was found in 9 to 54 per cent

Culture of *T hominis* is successful in media similar to those used for *E histolytica* Rats can be easily infected with *T hominis* but the susceptibility of different strains of rats varies (Hegner and Eskridge 1935)

Trichomonas Tenax (Muller 1773)

This flagellate is found in the human mouth in the tartar around the teeth and in the cavities of dental caries and in the pus of pyorrhea alveolaris (Gradwohl and Kouri 1948)

The morphology is similar to that of *T hominis* Whether or not they are the same species has been much discussed Wenrich (1931 1939) found certain morphologic differences which may be seen in Fig 9 Experiments by Bonestell (1936) and others confirm that we are dealing with distinct species

The incidence of this parasite appears to be rather high since Beatman (1933) found 22 7 per cent positive cases in 350 persons examined in Philadelphia It is supposed that transmission occurs in a manner similar to that of *E gingivalis*

Trichomonas Vaginalis Donné 1837

This species shows great morphologic similarity to the preceding species however some differences which can be seen in Fig 9 may be observed

It occurs in the vaginal mucus and reproduces by longitudinal binary fission Formation of cysts has not been observed Its nutritional requirements are still in dispute some authors assume that it lives upon bacteria or that it ingests red blood cells (Andrews 1929) Others (Bland et al 1932) believe that leucocytes are ingested by Trichomonas and in turn that Trichomonas are ingested by leucocytes

Transmission is venereal as well as by contact with contaminated objects

Although the pathogenicity of this organism is still a matter for discussion most authors hold it responsible for certain gynecologic conditions

Incidence appears to be high in both sexes. Andrews (1938) found an infection rate of 38 per cent Bland et al (1932) of 17 8 per cent in women Deo (1944) found 15 5 per cent of males infected He believes that the male is the transmitter and the female the reservoir

Cultivation of these organisms is successful in many media containing physiologic saline and protein material

Giardia Lamblia Stiles 1915

The body the major axis of which is approximately 10 to 20 microns is pear shaped with the wider part at the anterior end tapering to a point toward the posterior end From the posterior extremity project two tail like flagella If viewed from the side the organisms

have a concave structure, like a sucker, at the anterior extremity, this is the *cytostome* and serves to attach the parasite to the wall of the small intestine, producing irritation of the intestine

Infection occurs by ingestion of cysts which pass through the stomach and reach the small intestine

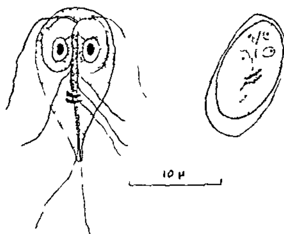

Fig 10 —Diagrammatic representation of *Giardia lamblia* At the left is a trophozoite at the right a cyst (Original drawing by T G de Beltrán)

Some authors deny a pathogenic role, others insist upon it There are reasons for assuming that it is pathogenic

This parasite is cosmopolitan although more common in high temperate regions We have found an incidence of 6 to 34 per cent

Chilomastix Mesnili (Wenyon 1910)

This organism measures 10 to 20 microns along its longer axis It also is pear shaped but is not bilaterally symmetrical

The posterior half of the body is often twisted It has a single nucleus relatively large and vesicular near the anterior extremity Near the nucleus there is a group of blepharoplasts from which arise three free anterior flagella Another flagellum, with the same origin, passes within the organism inside the cytostome the sides of which are supported by two small lateral fibrils

The cysts are lemon shaped, 6 to 9 microns long The nucleus, as well as remnants of the neuromotor apparatus, especially the flagellum within the cytostome, can be seen

These organisms inhabit the large intestine where they feed on bacteria and other minute particles Most authors do not believe that they play a pathogenic role The cysts appear to be exclusively a form of protection (Geiman 1935)

The incidence of C mesnili varies in different localities our investigations showing them as ranging from 10 to 25 per cent

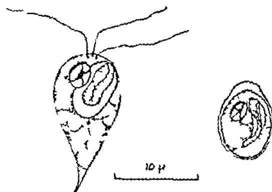

Fig 11 —Diagrammatic representation of Chilomastix mesnili At the left is a trophozoite at the right a cyst. (Original drawing by T C de Beltrán)

Enteromonas Hominis da Fonseca 1915

This is one of the smallest of intestinal flagellates of man measuring 4 to 8 microns They are of various shapes

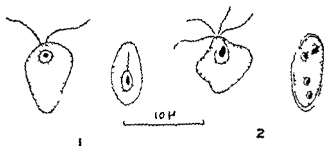

Fig 12 —Schematic representation of trophozoite and cyst of Retortamonas intestinalis, 1 and Enteromonas hominis 2 (Original drawing by T C de Beltrán.)

They have a single nucleus in the anterior extremity adjacent to a group of blepharoplasts from which originate the free flagella as well as another flagellum which extends along the length of the body without however forming an undulating membrane

The cysts are elongated from 6 to 8 microns long and present from one to four nuclei according to the stage of maturity

Little is known of their physiology and life cycle They are considered harmless in their relationship to man *Incidence is relatively low* in Mexico we have found 4 per cent

Retortamonas (Embadomonas) Intestinalis (Wenyon and O Connor 1917)

These flagellates are small 5 to 6 microns The parasite presents the form of a truncated cone with the flat extremity corresponding to the *cytostome*

in the anterior part It has a vesicular nucleus near the anterior extremity and two free flagella of unequal size

Cysts measure 4 to 6 microns and resemble those of *C mesnili*

This parasite seems to be harmless Incidence in our investigations never exceeded 3 per cent

INFUSORIA

These forms are characterized by vibratory locomotor appendages called cilia, which may partially or entirely cover the body and which at times combine to form composite organs of locomotion such as *membranellae* and *cirri*

The nuclear apparatus is composed of two distinct elements the *micronucleus* and the *macronucleus*, the first having a sexual function

A great number are parasitic Some forms such as *Ichthiophthirius multifilus* which parasitize the skin of certain fish may be important from the human point of view

One or more species of the genus Nyctotherus has been cited in man, but such references are now considered erroneous (Watchermann, 1938, Beltran, 1939) We recognize at this time but one infusorial parasite of man *Balantidium coli*

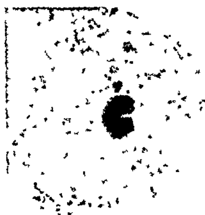

Fig 13 —Trophozoite of *Balantidium coli*, stained with Delafield hematoxylin Note the macronucleus in the center (X3 000) (Original photomicrograph of E Beltrán)

Balantidium Coli Malmsten 1857

This organism is ovoid and slightly tapered at the anterior end where a subterminal peristome is found It varies greatly in size, according to Hegner (1930) from 30 to 200 microns although the average size is 45 by 60 microns The cilia are arranged in longitudinal parallel lines around the body They are uniform except at the anterior extremity, where they become longer

The macronucleus situated near the central part of the body is usually reniform A small spherical *micronucleus* is found in its immediate vicinity There are two spherical contractile vacuoles situated laterally In the posterior portion there is a cytoproct or cytopyge subterminal and oblique Numerous food vacuoles may be observed, filled with bacteria and other material

Cysts, spherical and subspherical are about 50 microns in diameter, with a thick membrane with double contour Within the cyst there is a rounded mass of cytoplasm containing the nucleus

There is no agreement as to the details of the life cycle

B coli causes a severe form of dysentery The incidence is low Young (1937) reported that in the United States scarcely forty three cases of this infection are known to date and in Mexico (Beltran 1942) we found only sixty three although later more cases were recorded

Swine and various species of monkeys are often parasitized by *B coli*

SPOROZOA

These animals form a class represented exclusively by species that are parasitic

The only species which inhabits the human intestine is *Isospora hominis*, of the order Coccidia which parasitizes the epithelium of the digestive tract and its glands Members of this order usually present alternating generations with sexual and asexual phases which usually occur in the same host The infective forms are the spores which are resistant to external environmental conditions because of their protecting coverings

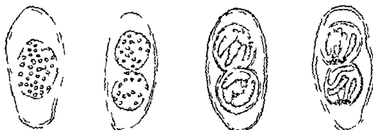

Fig 14 —Diagrammatic representation of successive stages in the development of the oöcysts of *Isospora hominis* (X3 000) (Original drawing by T G de Beltrán)

Fig 15 —Oöcyst of *Isospora hominis* immature (unstained specimen) (X3 000) (Original photomicrograph of I Beltrán)

Isospora Hominis Fantham 1917

Only their oocysts have been found the other stages of the life cycle being unknown *They are elongated with an ovoid contour frequently with* one of the extremities bottle neck shaped about 29 by 13 microns The sporocysts are formed within them with average dimensions of 12 microns, in these are observed when they mature four elongated sporozoites

Infection by this parasite appears to be rare Magath (1934) found in the literature only some 200 known cases In Mexico the first case was found recently (Beltran and Larenas 1944) Other cases were found later as yet unpublished

Little is known of its relationship to the host Most authors believe that it is pathogenic

CHAPTER 4

AMEBIC DYSENTERY, HEPATIC ABSCESS AND OTHER INTESTINAL CONDITIONS CAUSED BY PROTOZOA

Oscar Felsenfeld and Viola Mae Young

AMEBIASIS

DEFINITION

Amebiasis is the proper designation for invasion of the body by *Endamoeba histolytica*. In medical circles this term is rapidly replacing the obsolete "amebic dysentery," which is now applied only to that dysenteric syndrome which characterizes severe amebic ulcerative colitis. The use of the term "amebiasis" is substantiated by the necessity of including amebic abscess, subclinical conditions, and mild disease under the same heading as more serious illnesses caused by the same organism. Many writers have felt that neither the "symptomless" carrier state, nor certain cases in which the liver affection is of primary interest without apparent dysenteric symptoms or even diarrhea should be called "amebic dysentery." Thus the term "amebiasis" has been coined and accepted.

AGENT

Most authorities consider *E. histolytica* as the only pathogenic intestinal ameba. The morphology and life cycle of the ameba are described in Chapter 3. It must be emphasized here also that only the cysts of this organism are infective. The trophozoites are easily destroyed. Cysts, however, are able to remain alive for as long as three weeks in the feces. While boiling destroys cysts in a few seconds and temperatures of 6[illegible] to [illegible]0° C. are not resisted for five minutes, some cysts are able to survive at [illegible] to 4° C. for months. Chemical disinfectants do not destroy amebic cysts as quickly and reliably as they react on bacteria. Chlorine, for example, in a concentration of four parts per million parts of water must act for thirty minutes in order to destroy cysts. This action depends upon the temperature and the hydrogen ion concentration.

Not all strains of *E. histolytica* are equally resistant and virulent. Considerable work on the virulence of amebae was performed by Meleney and Frye (1933, 1936, 193[illegible], 1941) and Faust et al. ([illegible]). It may be stated that the pathogenicity of amebic strains varies considerably, those from [illegible] [illegible] generally being less virulent. There is also [illegible] [illegible] [illegible] of the amebae. The so-called "small form" or "small type" of *E. histolytica* was studied by Dobell ([illegible]), Andrews ([illegible]), Sapero et al. (194[illegible]), Frye and Meleney (1939) and others. Brumpt (193[illegible]) called it *Endamoeba dispar* and does not believe in its pathogenicity. [illegible] Young (1944) and Felsenfeld (1945) studied the "small type" in the midwestern United States. The cysts of this type are less than 10 microns in diameter. The trophozoites contain red blood cells only exceptionally. This variety is either only slightly pathogenic or nonpathogenic for cats and dogs. It causes only mild amebiasis. Later complications and intestinal perforation have never been observed in such infections. It disappears promptly after treatment with [illegible] preparations. In unstained preparations or in preparations stained with [illegible] it is easily mistaken for *Endolimax nana*.

TRANSMISSION

Patients with acute cases of *typical amebiasis, where only trophozoites* are excreted, do not transmit the disease as a rule. The real sources of infection are "symptomless carriers" or "symptomless cyst passers" and persons suffering from vague intestinal complaints which in a temperate climate may be mistakenly diagnosed as "*spastic colitis*," "*idiopathic* constipation," or "food allergy" and, therefore, are not being treated. Such persons, when working as food handlers, may cause many cases of amebiasis if viable cysts are harbored under their nails or carried on their soiled hands. In many tropical and subtropical countries where amebiasis is endemic, most of the food handlers have been found to be infected when surveys were made to detect the frequency of amebiasis.

In the Near East and in China, as well as in many other countries, mainly in the tropics, night soil is used as fertilizer. Vegetables grown under such conditions may be heavily contaminated with cysts and are a constant source of infection. Before marketing, vegetables are "freshened" by dipping into sewage. They become contaminated with cysts and serve *to spread amebiasis*.

Flies and other insects, such as cockroaches, often come in contact with fecal material and may mechanically transmit the infection with their legs or mouth parts. Flies, moreover, actually breed in feces. *If they swallow fecal material containing amebic cysts, they may* excrete such cysts for as long as three days. Insects carrying cysts often transfer the organisms to food, which, when consumed by susceptible persons, may cause infection.

Water is a frequent source of amebiasis. Its importance in the epidemiology of amebiasis was first recognized by Manson (1925) on Cape Verde, where he traced the infection to a well. Springs, unprotected wells, cisterns, and streams may contain contaminated water. Amebic cysts may be introduced into such sources of drinking water from seepage of sewage and by the use of contaminated drinking buckets or from infected persons swimming or washing in water which flows into such drinking water. The classical example of a water borne outbreak is that which occurred in Chicago during the Century of Progress Exposition. According to the committee report (1936), over 1,400 persons developed amebiasis, with about 100 deaths. The cause of the contamination of the water was a cross-connection between sewage and drinking water pipes in two large Chicago hotels.

Age seems to play a certain role in amebiasis. Faust (1942) and Craig (1944) stated that children have less opportunity and less time to acquire the infection. Ivanhoe (1943) studied the transmission of amebiasis in a home for children. This examination showed that under conditions favorable for the spread of the infection, that is, poor hygiene, crowding, etc., epidemiology in children does not differ from that in adults. Costa Mascaró (1945), Castelli (1944) and Tupas et al. (1946) found many cases of amebiasis in children and also in nurslings. In the observations of the senior author (1947) the youngest child with amebiasis was 16 days old; *this child had contracted his infection from a "cyst passer" grand*mother. The majority of patients however, are in the age group between 20 and 40 years.

Sex seems to be important; men are more often infected than women. This may, perhaps, be related to their occupations and hobbies, which lead them into situations where infection is more easily acquired (Manson Bahr, 1945).

Race is not a significant factor. Indigenous inhabitants, however, seem to suffer less from complications in highly endemic zones because they have developed partial immunity during earlier infections.

Seasonal incidence is observed because there are more flies during the warmer seasons, and, consequently, a greater number of mechanical transmissions occur. On the other hand, the rainy season in the tropics causes floods which rapidly spread infected feces over a wide area. Many exacerbations are observed after holidays and feasts, when individuals are apt to overeat, thus causing a relapse of the amebiasis.

The incidence of amebiasis was analyzed by Manson Bahr (1943), Craig (1944), Morton (1946), Cintra do Prado and Figliolini (1946), Klatskin (1946), Tallant and Maisel (1946), Elson et al. (1947), Felsenfeld and Young (1946 and 1948), and others. Craig (1944) gave

the average incidence of amebic infections in the United States as 8 1 per cent, while Faust (1942) estimated it to be as high as 20 per cent Recent regional investigations in the United States showed the following incidence of *E histolytica*

Wenrich and Arnett (1942)—12 per cent of food handlers and 10 7 per cent of student assistants in a Philadelphia school

Headlee and Calle (1942)—5 per cent among students in a Kentucky rural college

Nickel (1942)—4 4 per cent of the general population of Mississippi

Summers (1942)—4 per cent of the students in a Florida school

Browne et al (1945)—14 1 per cent among gastrointestinal patients in the New Orleans area.

Felsenfeld and Young (unpublished data)—9 per cent in inhabitants of Chicago

Incidence in state hospitals and other mental institutions seems to be high, mainly among the personnel working with amebic patients according to Burrows (1943) and Hopp (1944) The principal reason for the high infection rate, however, is the lowered hygienic habits of mental patients, the overcrowding and the generally poor living conditions in many mental hospitals Birnkraut et al (1945) found 11 5 per cent amebic infection in an asylum While 6 per cent of the employee food handlers harbored *E histolytica* 14 per cent of the patient food handlers were infected Castelli (1944), however, called attention to the fact that amebiasis is increasing not only among people living under bad hygienic conditions, but also among the rich and well to do

In South America former investigations revealed that 6 to 85 per cent of the population were infected with *E histolytica* Tropical regions are most heavily infested Beltrán (1942, 1944) and Beltrán and Larenas (1941, 1943) have shown that in Mexico the frequency of amebiasis varies from 7 to 47 per cent or higher according to locality and hygienic conditions. Ravelo Barré and Thomen (1943) found 14 per cent infestation in the Dominican Republic In Brazil Renault and Versiani (1940) do Amaral (1943) and Vello de Silva and Lopes Fontes (1944) reported a varying percent of the population infected, 8 33 to 40 per cent

In Europe, 1 to 10 per cent of the population are infected In Asia, the most heavily infested areas are in the south—Bengal, Bombay, and South China, respectively Many cases have been reported from North Africa fewer from tropical and South Africa Amebiasis is not often found among the inhabitants of Australia

PATHOLOGY

Endamoeba histolytica lives in the tissue of the intestinal wall which it penetrates with the aid of proteolytic ferments (called *cytolysins* by their discoverer, Craig) and by motility Those which do not enter the intestinal wall are discharged with the feces Faust (1941) offered conclusive proof that *E histolytica* cannot live in the lumen of the intestines and also that small lesions are found in the "cyst passers" who do not show symptoms of amebiasis Such lesions consisting of microscopic areas of cytolysis and superficial necrosis, are very often overlooked In order to be observed they must be carefully searched for by the pathologist Thus one should not use the expression "carrier" in amebiasis, because lesions are always present when cysts occur in the stools.

The invading amebae destroy the columnar epithelium of the large intestine and dig down into the crypts of Lieberkühn Finally they penetrate the basement membrane of the mucosa and enter the submucosa They engulf blood cells and remnants of tissue cells Cysts are never found in the tissues—only trophozoites

The microscopic picture of the lesions reveals stasis and capillary thrombosis, resulting in edema and necrosis Later, fibrosis may develop in the

TRANSMISSION

Patients with acute cases of typical amebiasis, where only trophozoites are excreted, do *not transmit the disease as a rule*. The real sources of infection are "symptomless carriers" or "symptomless cyst passers" and persons suffering from vague intestinal complaints which in a temperate climate may be mistakenly diagnosed as "spastic colitis," "idiopathic constipation," or "food allergy" and, therefore, are not being treated. Many exacerbations are observed after holidays and feasts, when individuals are apt to overeat, thus causing a relapse of the amebiasis.

The incidence of amebiasis was analyzed by Manson Bahr (1943), Craig (1944), Morton (1946), Cintra do Prado and Figliolini (1946), Klatskin (1946), Tallant and Maisel (1946), Elson et al. (1947), Felsenfeld and Young (1946 and 1948), and others. Craig (1944) gave

the average incidence of amebic infections in the United States as 8.1 per cent, while Faust (1942) estimated it to be as high as 20 per cent. Recent regional investigations in the United States showed the following incidence of *E. histolytica*:

Wenrich and Arnett (1942)—12 per cent of food handlers and 10.7 per cent of student assistants in a Philadelphia school.

Headlee and Cable (1942)—5 per cent among students in a Kentucky rural college.

Nickel (1942)—4.4 per cent of the general population of Mississippi.

Summers (1942)—4 per cent of the students in a Florida school.

Browne et al. (1945)—14.1 per cent among gastrointestinal patients in the New Orleans area.

Felsenfeld and Young (unpublished data)—9 per cent in inhabitants of Chicago.

Incidence in state hospitals and other mental institutions seems to be high, mainly among the personnel working with amebic patients according to Burrows (1943) and Hopp (1944). The principal reason for the high infection rate, however, is the lowered hygienic habits of mental patients, the overcrowding and the generally poor living conditions in many mental hospitals. Birnkraut et al. (1945) found 11.5 per cent amebic infection in an asylum. While 6 per cent of the employee food handlers harbored *E. histolytica*, 14 per cent of the patient food handlers were infected. Castelli (1944), however, called attention to the fact that amebiasis is increasing not only among people living under bad hygienic conditions but also among the rich and well to do.

In South America, former investigations revealed that 1.6 to 80 per cent of the population were infected with *E. histolytica*. Tropical regions are most heavily infested. Beltrán (1942-1944) and Beltran and Larcara (1941-1943) have shown that in Mexico the frequency of amebiasis varies from 7 to 4[illegible] per cent or higher according to locality and hygienic conditions. Ravelo Barré and Thomen (1943) found 14 per cent infestation in the Dominican Republic. In Brazil, Penault and Versiani (1940), do Amaral (1943) and Velho de Silva and Lopes Fontes (1944) reported a varying per cent of the population infected, 8.33 to 40 per cent.

In Europe 1 to 10 per cent of the population are infected. In Asia the most heavily infested areas are in the south—Bengal, Bombay and South China, respectively. Many cases have been reported from North Africa, fewer from tropical and South Africa. Amebiasis is not often found among the inhabitants of Australia.

PATHOLOGY

Endamoeba histolytica lives in the tissue of the intestinal wall, which it penetrates with the aid of proteolytic ferments (called *cytolysins* by their discoverer, Craig) and by motility. Those which do not enter the intestinal wall are discharged with the feces. Faust (1941) offered conclusive proof that *E. histolytica* cannot live in the lumen of the intestines and also that small lesions are found in the cyst passers who do not show symptoms of amebiasis. Such lesions, consisting of microscopic areas of cytolysis and superficial necrosis, are very often overlooked. In order to be observed they must be carefully searched for by the pathologist. Thus one should not use the expression "carrier" in amebiasis because lesions are always present when cysts occur in the stools.

The invading amebae destroy the columnar epithelium of the large intestine and dig down into the crypts of Lieberkühn. Finally they penetrate the basement membrane of the mucosa and enter the submucosa. They engulf blood cells and remnants of tissue cells. Cysts are never found in the tissues—only trophozoites.

The microscopic picture of the lesions reveals stasis and capillary thrombosis resulting in edema and necrosis. Later fibrosis may develop in the

vicinity In the beginning, when secondary bacterial infection is not present, leucocytes do not appear in the picture The amebae conglomerate near the edges of the ulcers, *in the crypts, and in the interglandular tissue* They often appear in "nests" *The amebae spread in the lymph spaces, in and along the thrombosed veins and capillaries, and gain access to the portal circulation, which carries them to the liver* This explains why the liver is the favored *site of amebic lesions*

The macroscopic picture is in agreement with this process *The first visible* lesions usually consist of yellow nodules localized mostly on the summits of the *mucosal folds* They contain viscid material, filling the cavity which has its

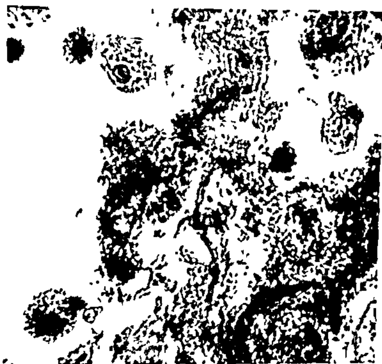

Fig 16 —Base of an amebic ulcer showing organisms (Original photomicrograph of Oscar Felsenfeld.)

base in the submucosa When such a lesion bursts into the lumen of the intestine, an ulcer, with undermined edges, narrow neck, and broad base, with a clean floor is formed This is the "flask shaped ulcer" When the ulcer spreads horizontally in the submucosa, a "buttonhole ulcer" *(bouton en chemise)* originates Small, superficial ulcers do not show inflammatory changes They are not undermined Many of them heal quickly and new ones are formed

Deep ulcers reach into the muscular layer They have thick, shaggy, swollen, much undermined, and elevated edges Fresh ulcers have rough and old ulcers clean bases There are numerous secondary hemorrhages, but

the mucosa between the ulcers has a grossly normal appearance Often sinuses are formed under the mucosa Sometimes the whole colon is covered with round ulcers, having raised undermined edges and white, fluffy bases These are known as 'sea anemone ulcers'

The entire colon may be covered with a dark exudate, the membrane may be undermined and burrowed This is called the 'seaweed colon.' Necrotic sloughs and remnants of more resistant supporting tissue on the base of deep ulcers are described as 'Dark hair sloughs' The intestine may resemble a buffalo skin

Fig 17 — Amebic liver abscess (Courtesy of Dr Paul B Szanto, Pathologist, Kankakee State Hospital)

Solitary isolated ulcers with hard margins which during life resemble malignant growths mainly when localized in the rectum are often found Amebic granuloma containing giant cells and amebae and resembling carcinoma is rarely observed

The walls of the intestine are often atrophic and dilated Even sacculation may occur between the ulcers Fibrosis mainly of the submucosa, leads to thickening of the intestinal wall Frequent combinations of atrophy and hyperplasia are observed

Secondary infections cause inflammatory changes The pathologic diagnosis of co existing bacillary and amebic dysentery may be very difficult *Anaerobic bacteria* mainly Clostridia so often abundant in the intestines may cause gangrene

Amebic ulcerations serve as a portal of entry for allergens which often cause allergic phenomena (Napier 1943 Klatskin 1946)

If the ulcers heal smooth depressed nonpigmented scars result The healing process includes formation of granulation tissue and rapid regeneration

Perforation of the ulcers occurs infrequently because of the protective hyperplastic proliferative reaction of the serosa of the intestines

According to Clark (1925) the lesions are most frequent and most extensive near the ileocecal valve in the flexures of the colon and in the rectum About 85 per cent of the patients show ulceration of the cecum and in about 60 per cent all parts of the lower bowel are affected About 20 per cent of the *patients do not have lesions in the rectum and sigmoid*

Fig 18 —Microscopic picture of liver abscess (Original photomicrograph of Oscar Felsenfeld)

The pathogenesis and pathologic physiology of the liver lesions have been minutely described by Manson Bahr (1943) They consist of foci of miliary necrosis or coalescent nonsuppurative areas, called liver abscess' Both may be solitary or multiple of variable size The liver abscess occurs most often in the right lobe and usually only one abscess develops No pyogenic membrane is found if the abscess is rapidly formed An old abscess has poorly defined connective tissue walls Charcot Leyden crystals hematoidin crystals fat globules cholesterol and remnants of tissue cells are found in the contents Amebae appear only in the living tissue The liver is enlarged Focal peritonitis and serous exudate are often seen Fatty degeneration and formation *of new bile channels are frequent*

The liver abscess may perforate into the abdominal pleural or pericardial cavities It may give rise to abscess formation in the lungs brain or other organs Skin lesions are rare and develop usually around amebic fistulae of the intestine Similarly urinary amebiasis is very unusual and originates most often following a perforation of the intestines or a perinephric or subphrenic amebic abscess into the kidneys or bladder (Watson, 1945)

CLINICAL SYMPTOMS

The *incubation time* is very irregular from a few days to several months

The clinical picture of amebiasis consists of many qualitatively and quantitatively different elements Several attempts have been made to classify the diverse clinical syndromes under which amebiasis presents itself Two of these classifications are most useful those of D'Antoni (1942) and Craig (1944) In the following pages the clinical picture of amebiasis will be discussed following closely D Antoni's division of the forms of this disease

One must realize that the clinical picture of amebiasis is governed not only by the actual extent of the pathology but also by a series of reflex and vasomotor changes induced by the lesions Triband (1934) showed that the sympathetic system is of paramount importance in the production of the nervous manifestations in amebiasis In addition toxic and allergic phenomena play a role These are due to the disintegration of the amebic tissue to the activity of secondary invaders and to the absorption of allergens through the ulcers In the last five years we have examined bacteriologically and parasitologically stools from more than 700 patients with amebiasis In only 3 per cent of them were we unable to find secondary invaders such as Proteus paracolon organisms flagellates and others It must be considered that these organisms may add to the general so called toxic symptoms so often observed in amebiasis

Craig (1944) stated that amebiasis always causes clinical symptoms even in the so-called "symptomless carrier state" but these complaints may be so mild and the patient so accustomed to them that he either does not pay any attention to them or attributes them to some other cause

Subclinical Amebiasis

This is the symptomless carrier or cyst passer state Most of the patients do not apply for medical care and if they do they generally come to the physician s office or to the clinic for other reasons The majority of such cyst passers are discovered by parasitologic surveys on routine gastrointestinal check ups and when an investigation is carried out by public health authorities to discover the source of infection of a clinically manifest case Upon questioning some cyst passers reveal vague general symptoms such as lassitude fatigue occasional headaches irritability disturbances of sleep and appetite vasomotor manifestations such as a feeling of cold in the extremities palmar perspiration palpitation etc These symptoms as Craig (1944) pointed out are not at all typical of amebiasis If caused by *E his tolytica* however they disappear after antiamebic treatment

The danger of subclinical amebiasis is twofold First clinical symptoms may develop when the host parasite relationship is disturbed There seems to be an equilibrium established between the invading amebae and the defense mechanism of the body of the host If this equilibrium is disturbed in favor of the parasites the process spreads causing amebic dysentery and even liver

abscess Cases of amebiasis of the liver which have developed without clinic intestinal signs and in which practically no bowel lesions are seen origina from symptomless carrier states

Second the carrier is a dangerous source for the spread of amebiasis A stated above the disease is transmitted only by cysts Therefore the cy passer is an effective propagator of amebiasis mainly when he is a foo handler—cook waiter food store clerk marketing vegetable gardener or farme dairy worker etc Under lowered hygienic conditions the stools of a cy passer may contaminate supplies of water used by other people Because o the large number of such cyst passers among the population of the America no effective antiamebic program is possible unless they are cured

Symptomatic Amebiasis—Syndromic Amebiasis

Amebiasis With Prevailing Constipation—Simon (1934) Howard (1939) Manson Bahr (1943) Craig (1944) Lopes Pontes (1945) and others emphasiz *constipation as an outstanding symptom in many cases of amebiasis* In th type of amebiasis designated here as amebiasis with prevailing constipation constipation usually dominates the picture There are however diarrhea episodes mostly in the early morning hours These attacks may be instigated or initiated by certain foods and may be attributed to food allergy or a nerv ous upset may lead to their occurrence Excessive indulgence in alcohol may also bring on an attack The patient is awakened by the necessity for evacu ation of the bowels Pain is usually present either diffuse or localized in the lower abdomen. The pain may even be colicky Colic however is not re ported in very many cases One or more stools terminate the attack These are copious but as a rule do not contain blood or mucus The number of bowel movements does not exceed three to four per day The diarrhea lasts only one or two days Following it constipation commences which is again interrupted by a new attack of diarrhea after a period of two or more weeks to months

Constipation with a consecutive diarrheal attack is also observed It is *characterized by mild epigastric pain or feeling of pressure mainly after* meals and moderate hyperchlorhydria thus resembling gastric or gall bladder disease This form often observed in the Midwestern United States was re cently described in Brazil by Lopes Pontes (1945a)

Distention particularly after eating is a common complaint in amebiasis It is caused by the accumulation of gas and is the source of much discomfort Distressing flatulence and borborygmus are present usually involving the right side of *the abdomen Manson s sign the amebic splash* that is sensa tion of fluidity upon palpation is often observed Discomfort distress or pain may appear in paroxysms lasting one or more hours The pain may re main localized or it may migrate

Gastric disturbance resulting from the distention and consequent reflex pain is frequent The appetite may be capricious *Dislike of certain foods* is not unusual

There is no fever. On the contrary, the temperature trend is toward the subnormal, falling in the morning to 96° or 97° F. (35.5° to 36° C.) as pointed out by Craig (1944).

The general symptoms connected with this type are those described under the heading Subclinical Amebiasis. Lack of concentration and memory, sleeplessness or sleepiness, especially in the morning, and headache in the early hours are very frequent in this type of amebiasis.

These clinical symptoms explain why this disease is often mistaken for nervous irritable or spastic colon, food allergy, neurasthenia, duodenal ulcer, chronic gastritis, and other conditions.

The stools do not show blood, except in very rare instances. A few leucocytes and pyknotic nuclei may be present. Much undigested food is present during the diarrhea. Often several specimens, including postcathartic stools, must be examined before the amebae are discovered. Manson-Bahr (1943) recommended that the feces adhering to the rectal mucosa be examined for cysts. The authors have found this a very helpful procedure.

Amebic Diarrhea. This type differs from the former in the development of a more expressed diarrheal pattern. The disease begins suddenly or slowly. The first attack of diarrhea or the recurrent attack may be caused by many factors, such as excess food, alcohol, nervous upset, etc. The attack is similar to that described under Amebiasis With Prevailing Constipation, except that the stools may be more numerous, as many as ten a day, the average being three to five. In addition, the attack lasts for several days, the stools remaining semifluid for some time. It is not uncommon for constipation of a short duration to follow, mainly in cases treated with intestinal absorbents and astringents.

Colic is usually present. The attacks are terminated by the evacuation of copious light colored or very dark, frequently semifluid stools, with mucus and a few leucocytes. There is definite relief after the evacuation of the stool. Usually much gas accompanies the feces.

The colic or the pain may be diffuse or localized. If localized, the favored sites are in the following order: over the cecum, sigmoid, descending colon, transverse colon, and lumbar region. The sigmoid is sensitive upon deep pressure. This is Manson's "amebic signpost."

The pain often shows definite changes. It may increase with cramps of short duration, changing into a feeling of deep pressure and distention. There is much gas, flatulence, and borborygmus. Flatulence may be the most outstanding complaint of the patient.

The pain may depend upon meals. In many cases there is a feeling of fullness and distention after meals and pain appears within a few hours thereafter. There is no tenesmus.

A mild elevation of the temperature, without great changes in the blood picture, may be observed on the first day of the diarrheal attack. It usually reaches 100° F. (38° C.).

Gastric disturbance and changes in the appetite are present in many cases. While the types of amebiasis described above do not cause loss of weight, this

is observed in amebic diarrhea mainly during the hot season This loss is often compensated during the winter months The nervous symptoms are the same as in the preceding types of amebiasis

The stools contain mucus some leucocytes and pyknotic bodies Many tissue cells yeasts and mold spores are common If the disease is of longer duration Charcot Leyden crystals are not rare

The clinical symptoms of amebic diarrhea must be differentiated from *chronic mucous colitis* *In amebiasis* strings or casts of the bowel are never evacuated Finding amebae will establish the diagnosis Ulcerative colitis and *carcinoma* the *latter resembling solitary amebic ulcers must be differentiated* also by the aid of x ray and proctoscopic examination Intestinal tuberculosis may cause many symptoms *simulating amebiasis* *Constant elevation* of temperature loss of weight lung findings and stool examination will determine the diagnosis It must be pointed out that in the authors' experience the intestines of persons with carcinoma or diseases involving the blood forming organs such as leucemia Hodgkin's disease etc are often invaded by *E histolytica* Therefore if amebae are found they should not be considered as the exclusive factor for other diseases may be present One must keep in mind too that there are no diseases there are only sick people

Intermediate Type of Amebiasis—Many cases of amebiasis cannot be classified The dividing line between the two preceding types is the duration of the diarrhea and the composition of the stools One finds a number of cases which at times show the characteristics of one and at times features of the other type Such cases should be classified as intermediates The most common *of these is the seasonal type* *After excessive eating or consumption of* alcohol often at the time of national or religious celebrations the diarrheal *course develops* with mucus in the stools Then the pattern of constipation is followed through the intervening months reverting to the diarrheal type after new excesses

Irregular bowel action without frank diarrhea with enterospastic symptoms and weakness after defecation as described by Browne et al (1945) is another frequent manifestation of amebiasis which must be classified as an intermediate type

Acute and Chronic Amebic Dysentery—This is the classical amebiasis mostly observed in hot climates and often becoming manifest in persons recently arriving from the tropics

The onset is sudden or gradual If gradual the disease begins with a mild *diarrhea later evacuation of feces* with mucus and blood develops Colic and tenesmus are usually absent during the acute stage Tenesmus may *develop later* as a result of anal irritation The pains may vary in intensity

In cases with sudden onset the pain is generally intense and localized in the same regions as in amebic diarrhea The stools are copious and always contain fecal material In very acute cases as many as twenty five to thirty bowel movements a day are observed The majority however have about five to fifteen stools per day They contain blood streaked mucus *When the* blood is greatly altered and intermingled with mucus and feces " anchovy

sauce" stools are observed. Pinhead sized particles of bloody mucus simulate "sago grains." *Decomposed blood may give the feces a very dark discoloration.*

There is much abdominal discomfort, feeling of distention and pressure. Flatulence is common.

According to Mukherjee (1942) fever is present in about 10 to 15 per cent of the cases. It occurs more frequently in acute forms. It reaches 100° to 101° F (38° to 38.5° C). There is a definite loss of weight during the disease.

In fulminating cases, gangrene of the intestines develops due to secondary infection. In other cases the ulcers penetrate rapidly and cause perforation of the blood vessels with extensive hemorrhages. They may break through the intestinal wall and initiate peritonitis. This form is fortunately rare, and ordinarily a chronic state develops.

Chronic amebic dysentery is characterized by general symptoms as previously described. *Abdominal discomfort and flatulence cause great distress.* There is usually localized pain, mostly above the cecum or sigmoid. The number of stools is increased, or constipation alternates with diarrhea. There may be persistent low grade fever resembling brucellosis or tuberculosis. Intermittent fever with peaks as high as 102° to 104° F (39° to 40° C) has also been reported. During the attack of diarrhea the stools show the characteristics of dysenteric feces: they contain various amounts of mucus and blood.

If the disease is not treated, further developments with several courses may be observed.

In unfavorable cases, loss of weight continues. A "myxinoid" inelastic skin develops. Sequelae and complications arise which kill the emaciated patient.

In more favorable cases the disease may revert to a milder form. Frequently a subclinical state is the outcome. In other instances a type with constipation develops.

As to the differential diagnosis, the classical picture is easily recognized if stool examinations are made. The acute form may resemble typhoid or Salmonella fever. However, the spleen is not enlarged in amebiasis. Differentiation from bacillary dysentery in cases with acute onset and tenesmus may be very difficult. Laboratory examination of fresh stools for both parasitic and bacillary incitants of diarrhea will solve the differential diagnosis.

Amebiasis With Localized Symptoms. *There are forms which are more or less confined to certain segments of the bowel in such a way that the resulting symptoms closely resemble other diseases.* Most important of the manifestations of amebiasis are the following forms:

Amebic Typhlitis and Appendicitis. Because more than 80 per cent of the amebic lesions involve the cecum, symptoms in this region of the bowel are not at all rare. A picture clinically resembling subacute appendicitis is a common feature. When the course is subacute or chronic, pain localized in that region is the *most outstanding symptom.* *Acute amebic ulcers may cause* elevation of temperature to 100° to 102° F ([illegible] to 39° C). Pain is always

present Nausea may be one of the complaints While the pain is localized in the right iliac fossa there is little alteration of the pulse and of the respiration The number of white blood cells may be increased If the number exceeds 15 000 to 16 000 secondary infection must be suspected Such an invasion also causes symptoms of peritoneal irritation to a marked degree so that all clinical signs of such an involvement—signs of Ploenius Rovsing and Blumberg—become strongly positive The differential diagnosis of amebic typhlitis and appendicitis from other diseases of these portions of the bowel is of paramount importance because operation upon the amebic intestines leads to rupturing sutures fistula formation cutaneous amebiasis etc Finding amebae in the stool and prompt reaction of the patient to emetine permit avoidance of grave consequences

Amebic Granuloma—Amebic granuloma is a condition often mistaken for malignancy because the proctoscopic and x ray pictures resemble that of annular carcinoma This condition was recently discussed by Reddy and Rangam (1946) and Silverman and Leslie (1947) Examination of biopsy material will determine the diagnosis as suggested by Smyth (1946)

Amebiasis Resembling Cholecystitis—True amebic cholecystitis is very rare Most strains of amebae are killed by bile But when the lesions are localized in the splenic flexure of the colon or in the transverse colon the symptoms may closely resemble cholecystitis with or without cholelithiasis There is a feeling of pressure dull pain or even cramps in the right upper quadrant often irradiating dorsally and caudally The pressure or the pain becomes worse after meals Intermittent diarrhea may be present For the differential diagnosis the following features are important The typical attack of cholelithiasis causes much stronger pain than does amebiasis Amebiasis only rarely shows icterus On palpation the point of pain is more localized in cholecystitis than in amebiasis Laboratory examination is of the utmost value

Amebiasis Resembling Ulcers of the Stomach or of the Duodenum—Pain beginning two or three hours after meals is often present in mild forms of amebiasis When the pathology is localized in the transverse colon there may be sensitivity to pressure under the xiphoid process of the sternum or to the left side of it In other cases there is heartburn with hyperacidity pain between or shortly after meals feeling of fullness with constipation and dark stools

Other types are relatively rare

Complications

The manifold complications of amebiasis may be divided into intestinal and extraintestinal types

Perforation—These are not very frequent In North America they occur only in about one out of one thousand cases of amebiasis They may develop suddenly or slowly according to the thickening of the wall and peritoneal reactive processes in the vicinity The perforations are usually in the cecum

appendix or rectum *They may be single or multiple* The result depends upon the site of the perforation Most frequent are perforations into the peritoneal cavity causing peritonitis *Perforations into the pericardium and* urinary tract are rare Slowly developing perforations may cause pericolic perirectal, or perinephritic abscess

A sudden perforation is revealed by pain, or colic distention of the abdomen vomiting collapse There is an increase in the pulse rate and in the respiration The temperature may remain subnormal during the first hours Manson Bahr (1943) pointed out that in toxic patients the symptoms are not always so dramatic and the spreading of tenderness may be the only sign of perforation We saw several cases in which the onset of the perforation could *not be diagnosed except for the sudden change in the stools which became* glassy like and consisted of a mixture of mucus and blood without other material *normally present in the feces The perforation of amebic typhlitis or appendi*citis cannot be distinguished from perforations caused by other forms of appendicitis Rectal perforation may be seen through sigmoidoscopy

Abscess formation does not necessarily cause many clinical symptoms if the abscess is small Changes in the blood picture are more extensive when secondary infection is present

Hemorrhage—Hemorrhages originate from the erosion of vessels at the bases of intestinal ulcers Small hemorrhages may be observed also in patients with hemorrhoids when these bleed during an attack of amebic diarrhea or dysentery Hemorrhages always must be carefully investigated and treated accordingly

Amebic Hepatitis—Hepatitis occurs in 0 1 to 5 per cent of cases with amebiasis In the northern parts of the United States where the smaller type of *ameba causes most of the infections hepatitis is very rare Excellent reviews* of this complication were published by Warshawski et al (1946) and Klatskin (1946) *Klatskin (1946) distinguishes the following types acute subacute* and chronic hepatitis which must be differentiated from amebic abscess

The onset is usually sudden There are however cases of intestinal amebiasis with unexplainable short chills which later develop into the classical picture of amebic hepatitis Manson Bahr (1943) believes that chills result from periodic invasions of the liver by amebae There is irregular fever especially in the acute form frequently reaching 102° to 104° F (38° to 39° C) often accompanied by sweating mainly at night The liver is enlarged and painful The pain frequently irradiates mostly to the shoulders less often to the back or upward it increases upon movement pressure inspiration and cough and sometimes by lying on the side While toxic icterus may be present it is an exception rather than the rule The number of white blood cells is frequently between 15 000 and 0 000 The number of mononuclear cells is decreased The sedimentation rate of the red blood cells is increased

Diarrhea is observed in many cases but may be absent Nausea and vomiting are frequent *Cough may be an outstanding symptom*

The attack may subside after a few days or may precede the development of a liver abscess Relapses may occur *or a chronic form may develop*

The subacute and chronic forms show less pain little or no fever and in some cases little or no change in the blood picture

The acute form must be differentiated from amebic liver abscess and other conditions In acute cholecystitis and cholangitis bile pigments are found in the urine A positive van den Bergh reaction and a high icteric index are discovered upon examination of the blood serum Icterus is also present as a rule

The subacute chronic and recurrent types must be distinguished from malaria brucellosis chronic cholecystitis liver cirrhosis stasis in heart disease schistosomiasis and other conditions

Amebic Liver Abscess (Figs 17 and 18)—Craig (1944) reported liver abscess in 5 per cent and Manson Bahr (1943) in 2 to 5 per cent of the cases of amebiasis It is usually a late complication of amebiasis and may also develop in cases where amebae are not found in the intestinal contents

Newcomers to the tropics are more subject to liver abscess than persons born in such a climate Excessive use of alcohol malnutrition and debilitating diseases likewise are predisposing factors for this complication

The acute form with symptoms closely resembling amebic hepatitis is less frequent Usually multiple abscess formation causes the acute symptoms The pain is often relieved by lying on the right side The number of white blood cells is lower according to Klatskin (1946) higher than in amebic hepatitis *There is often nausea or vomiting Diarrhea is frequently absent Coughing* is a usual complaint

The more frequent chronic form begins with a feeling of pressure Later pain develops which often irradiates as the pain in amebic hepatitis It may be more intensive at night The fever is low at the onset reaching its peak *in the evening* Later chills may develop Night sweats may accompany the drop in temperature which becomes normal or even subnormal in the morning Gastric and intestinal disturbances may be absent *The sedimentation rate of* the red blood cells is often increased Cough may cause much complaint The abscess frequently localizes in the right lobe There is pain on palpation and pressure loss of weight and indigestion Pressure of the abscess on the bile channels may, in rare instances cause icterus Any part of the liver may *show enlargement* The right diaphragm is frequently elevated and its movements limited In other cases the lower liver border is shifted caudally Enlargement of the left lobe may cause pressure or simulate enlarged spleen Irritation of the diaphragm and the pleura causes coughing as well as exudation and even compression of the right lower lobe

The abscess may perforate into the abdominal cavity or more often into the lung *If perforation* does not terminate the disease emaciation is the usual cause of death *Only 15 to 30 per cent* of unoperated patients survive

The number of white blood cells is between 10 000 and 35 000 Da Silva (1945) states that the larger the abscess the lower the cell count

When the liver abscess is secondarily infected the fever and the leucocytosis are high Differential diagnosis may be very difficult in such cases

Problems of differential diagnosis are numerous In acute amebic hepatitis there is more pain on palpation The liver is always enlarged in toto while in amebic abscess as a rule only parts show an increased volume Suppurative cholecystitis likewise must be differentiated Pleurisy, chronic pneumonia empyema and tuberculosis may be distinguished by x ray examination Carcinoma of the liver may cause great diagnostic difficulties Subphrenic abscess from perforated ulcers shows gas under the diaphragm Infected hydatid cysts and undulant fever may be excluded by laboratory tests Kala azar malaria and typhoid fever produce leucopenia and spleen enlargement

Other Localizations of the Amebic Abscess — Amebic abscess of the lung is usually due to a liver abscess It contains chocolate colored pus which is expectorated early in the disease Later the pus becomes more of a yellow color and contains Charcot Leyden crystals The x ray examination shows a picture similar to bronchopneumonic consolidation Fever may or may not be present The white blood cell count is high There is pain cough and hiccup The condition is nearly always fatal

The same is true of brain abscesses which cause symptoms according to their localization Abscess of the spleen epididymis and penis and paranephritic abscess have also been described

Cutaneous Amebiasis —This condition recently analyzed by Wilson and Hurewitz (1946) seldom develops The usual site is around the anus or after operation establishing an artificial anus in an amebic intestine or open drainage Punched-out ulcers or irregular spreading ulcerations with granulating painful bases are observed

Urinary Amebiasis —It is an accepted fact that such types of amebiasis are very rare They occur as sequelae of perforation of an amebic intestine or abscess into the genitourinary system according to Watson (1945 1945a) Amebiasis of the sexual organs is rare

Sequelae

Progress of amebiasis may lead to permanent changes in the intestine These together with the reactions of the autonomic nervous system discussed and classified recently by Lopes Pontes (1949a) and allergic phenomena create a number of changes causing the patient considerable distress

Spastic Colon —Spastic colon indistinguishable from spastic or "irritable" colon of other origin may result from amebiasis It develops chiefly in persons who have suffered from much constipation during the amebiasis There are spastic contractions of the colon particularly of the descending large bowel These contractions alternate with periods of relaxation even hypoactivity of the colon This sequel is very frequent in North America

Mucous Colitis —Manson Bahr (1945) emphasizes this sequel In our observations of mucous colitis which develops in amebiasis there are not many eosinophiles in the stools Finding of large casts of the bowel in the feces is also rare Varying amounts of mucus are expelled with the stools which may vary from day to day in the same patient

The subacute and chronic forms show less pain, little or no fever, and in some cases little or no change in the blood picture

The acute form must be differentiated from amebic liver abscess and other conditions In acute cholecystitis and cholangitis bile pigments are found in the urine A positive van den Bergh reaction and a high icteric index are discovered upon examination of the blood serum Icterus is also present as a rule

The subacute chronic and recurrent types must be distinguished from malaria brucellosis chronic cholecystitis liver cirrhosis stasis in heart disease schistosomiasis and other conditions

Amebic Liver Abscess (Figs 17 and 18) —Craig (1944) reported liver abscess in 5 per cent and Manson Bahr (1943) in 2 to 5 per cent of the cases of amebiasis. It is usually a late complication of amebiasis and may also develop in cases where amebae are not found in the intestinal contents

Newcomers to the tropics are more subject to liver abscess than persons born in such a climate Excessive use of alcohol malnutrition and debilitating diseases likewise *are predisposing factors for this complication*

The acute form with symptoms closely resembling amebic hepatitis is less frequent Usually multiple abscess formation causes the acute symptoms The pain is often relieved by lying on the right side The number of white blood cells is lower according to Klatskin (1946) higher than in amebic hepatitis There is often nausea or vomiting Diarrhea is frequently absent Coughing is a usual complaint

The more frequent chronic form begins *with a feeling of pressure* Later, pain develops which often irradiates as the pain in amebic hepatitis It may be more intensive at night The fever is low at the onset reaching its peak in the evening Later chills may develop Night sweats may accompany the drop in temperature which becomes normal or even subnormal in the morning Gastric and intestinal disturbances may be absent The sedimentation rate of the red blood cells is often increased Cough may cause much complaint The abscess frequently localizes in the right lobe There is pain on palpation and pressure loss of weight and indigestion Pressure of the abscess on the bile channels may in rare instances cause icterus Any part of the liver may show enlargement The right diaphragm is frequently elevated and its movements limited In other cases *the lower liver border is shifted caudally* Enlargement of the left lobe may cause pressure or simulate enlarged spleen Irritation of the diaphragm and the pleura causes coughing as well as exudation and even compression of the right lower lobe

The abscess may perforate into the abdominal cavity or more often into the lung If perforation does not terminate the disease emaciation is the usual cause of death Only 15 to 30 per cent of unoperated patients survive

The *number of white blood cells* is between 10 000 and 35 000 Da Silva (1945) states that the larger the abscess the lower the cell count

When the liver abscess is secondarily infected the fever and the leucocytosis are high Differential diagnosis may be very difficult in such cases

Problems of differential diagnosis are numerous In acute amebic hepatitis there is more pain on palpation The liver is always enlarged in toto while in amebic abscess as a rule only parts show an increased volume Suppurative cholecystitis likewise must be differentiated Pleurisy chronic pneumonia empyema and tuberculosis may be distinguished by x ray examination Carcinoma of the liver may cause great diagnostic difficulties Subphrenic abscess from perforated ulcers shows gas under the diaphragm Infected hydatid cysts and undulant fever may be excluded by laboratory tests Kala azar malaria and typhoid fever produce leucopenia and spleen enlargement

Other Localizations of the Amebic Abscess—Amebic abscess of the lung is usually due to a liver abscess It contains chocolate colored pus which is expectorated early in the disease Later the pus becomes more of a yellow color and contains Charcot Leyden crystals The x ray examination shows a picture similar to bronchopneumonic consolidation Fever may or may not be present The white blood cell count is high There is pain cough and hiccup The condition is nearly always fatal

The same is true of brain abscesses which cause symptoms according to their localization Abscess of the spleen epididymis and penis and paranephritic abscess have also been described

Cutaneous Amebiasis—This condition recently analyzed by Wilson and Hurewitz (1946) seldom develops The usual site is around the anus or after operation establishing an artificial anus in an amebic intestine or open drainage Punched out ulcers or irregular spreading ulcerations with granulating painful bases are observed

Urinary Amebiasis—It is an accepted fact that such types of amebiasis are very rare They occur as sequelae of perforation of an amebic intestine or abscess into the genitourinary system according to Watson (1945 1945a)

Amebiasis of the sexual organs is rare

Sequelae

Progress of amebiasis may lead to permanent changes in the intestine These together with the reactions of the autonomic nervous system discussed and classified recently by Lopes Pontes (1945a) and allergic phenomena create a number of changes causing the patient considerable distress

Spastic Colon—Spastic colon indistinguishable from spastic or 'irritable' colon of other origin may result from amebiasis It develops chiefly in persons who have suffered from much constipation during the amebiasis There are spastic contractions of the colon particularly of the descending large bowel These contractions alternate with periods of relaxation even hypoactivity of the colon This sequel is very frequent in North America

Mucous Colitis—Manson Bahr (1945) emphasizes this sequel In our observations of mucous colitis which develops in amebiasis there are not many eosinophiles in the stools Finding of large casts of the bowel in the feces is also rare Varying amounts of mucus are expelled with the stools which may vary from day to day in the same patient

Postamebic Gastrointestinal Disturbances—This condition may be characterized by hyperchlorhydria or by hypochlorhydria. It is the result of a combination of the nervous disturbances to which the lessened ability of the diseased intestines to absorb the B vitamin complex (Ascoli 1946) adds further reasons for dysfunction. As in the preceding conditions it may originate *during the* actual amebiasis and become predominant during convalescence. It often presents therapeutic difficulties, especially if for some reason an adequate diet cannot be sustained.

Intestinal Ulceration—Manson Bahr (1945) points out that ulcers of the small intestine may appear as a sequel to amebiasis.

Chronic ulcerative colitis of the large bowel is *often* observed either as a complication or as a sequel to amebiasis. Secondary infection and disturbances of bowel innervation play a major part in its development. The clinical picture does not differ from that of the so called "idiopathic" ulcerative colitis.

Fig 19.—Amebic colon showing typical ulcerations. A defect penetrating the entire wall is due to the great fragility of this diseased tissue. (*From the collection of R. B. H. Gradwohl.*)

Hill Diarrhea and Sprue—While many authors consider these conditions as separate entities *sui generis*, others see amebiasis as the cause. Hill diarrhea like conditions of *different intensity* are often observed immediately following amebiasis. Disturbances of fat absorption are not rare in chronic amebiasis.

Malformations of the Colon—Strictures and stenoses are rarely sequelae of amebiasis. Rather dilatations and diverticula tend to develop. Megacolon has been observed. These conditions *are diagnosed by x ray*.

Diseases of the Rectum—Prolapse of the rectum and hemorrhoids are not infrequent, particularly in long-standing cases. Periproctitis with or without abscess formation may result chiefly in patients with extensive secondary infections.

Malignancy—Manson Bahr (1945) calls attention to carcinomatosis originating in amebic and postamebic lesions Reed and Anderson (1936) described a number of cases with malignancy observed after amebiasis This sequela however seems to be rare

Nephritis—Interstitial nephritis is often observed in fatal cases of amebiasis Nephritis may develop during the acute phases of amebiasis and is frequently overlooked if periodic urine examinations are not carried out The pain in the back may be attributed to the diseased intestines which holds true in most patients who complain of such pain A latent nephritis is frequently discovered through the use of nephrotoxic drugs in the treatment of the amebiasis

Neurasthenia—Neurasthenia acompanies all types of amebiasis Craig (1944) stated that many cases of ' tropical neurasthenia ' are caused by amebiasis

SIGMOIDOSCOPIC EXAMINATION

Manson Bahr (1945) found lesions during sigmoidoscopy in about 50 per cent of his cases Browne et al (1945) in about 18 per cent Karl and Sloan (1946) in about 30 per cent Many cases do not show such changes The lesions are often microscopic and must be observed according to Manson Bahr s recommendations through a magnifying glass

One must emphasize that the sigmoidoscopic findings are often not paralleled by the clinical picture Sometimes extensive lesions and only few clinical symptoms are observed while in other cases scant pathology will be manifested by severe clinical features

The rectosigmoidal junction and Houston s valves are the most frequent sites of visible lesions

Often only small elevations with hyperemic margins are seen There may be small depressions granular patches or scattered hemorrhages An unchanged mucosa between the lesions is typical of amebiasis where secondary infection has not taken place

Typical ulcers with undermined edges easily bleeding bases and hemorrhagic margins covered with exudate and debris may be seen Large solitary ulcers are rarely observed When they do occur their usual location is just inside of the anal margin They are painful and bleed easily When the ulcers spread they may coalesce and form larger easily bleeding defects

X RAY EXAMINATION

Vallarino (1925) called attention to filling defects in amebiasis Weber (1933) and Bell (1938) consider a cone shaped deformed cecum characteristic of amebiasis Ikeda (1934) stated that the x ray picture differs according to the type of amebiasis that is if ulcerative fibrous or granulomatous processes predominate Recently Walbur and Camp (1946) and Arendt and Cohen (1948) revised the roentgenology of amebiasis with the aid of studies of the mucosal pattern Deformities of the cecum were often found A

g 20 — X ray picture of bowel in amebiasis (Courtesy of Dr Arendt and Dr Cohen and the Am J Roentgenol & Radium Therapy, 1946)

21 — X ray picture of bowel in chronic ulcerative colitis (Courtesy of Dr Arendt and Dr Cohen and the Am J Roentgenol & Radium Therapy 1946)

barbed wire appearance of the bowel similar to that seen in irritable colon" was observed In addition swelling and widening of the mucosal folds their disorientation chiefly in the ascending colon and cecum, were present The mucosal folds ascended with sharp angles Soft double outlines showed swollen intestinal walls Localized spasm over the cecum and ascending colon with irregular feathery pattern was frequently seen In other cases a narrowing of the sigmoid was observed A wider system with fewer mucosal folds caused a paucity of the mucosal pattern in many cases. When chronic ulcerative colitis entered the picture mucosal denudation in the descending colon developed In other cases wall defects fibrosis contraction and absence of haustration or a corkscrew type of incomplete haustration were seen

Arendt and Coheen (1948) found a mild degree of mucosal irregularity also in *Dientamoeba fragilis* and *Iodamoeba butschlii* infections

Fig * —X ray picture of bowel in bacillary dysentery (Courtesy of Dr Arendt and Dr Cohen and Am J Roentgenol & Rad'n Therapy 1946)

LABORATORY FINDINGS

Stool Examination

The laboratory proof of amebiasis is the finding of *E histolytica* As a rule in formed stools one finds cysts while in liquid stools trophozoites predominate

The methods of examination are described in detail in Chapter 71 and by Gradwohl (1948)

It is imperative to examine every stool for both parasitic and bacillary irritants of diarrhea

The cellular composition of the fecal material may give a hint as to the diagnosis In the beginning of amebiasis the exudate contains only a few

leucocytes and extruded *nuclei of white blood cells called* 'pyknotic bodies' by Callender These bodies are a constant finding in clinically manifest amebiasis If red blood cells are present in larger numbers they may show clumping During the later development of amebiasis Charcot Leyden crystals may appear Manson Bahr (1945) warns against overestimating their importance They *are not specific for amebiasis Undigested food* mycotic elements and many epithelial cells are frequently found When secondary infection develops the picture may be changed

Amebae usually disappear from the stools during a severe intercurrent bacillary intestinal disease such as *typhoid or Shigella dysentery When* these conditions clear the amebae reappear *Exceptions however, are often* encountered when *E histolytica* is found and simultaneously Salmonellae or Shigellae are cultivated

In order to be able to evaluate the results of therapy, the first stools after treatment must not be taken sooner than five days after discontinuation of the therapy Three examinations should be performed one week apart Then for six months monthly examinations are advised When the lesions are restricted to the upper parts of the large bowel postcathartic stools are preferred

Complement Fixation Tests

In cases where amebae are not found and suspicion of amebiasis persists complement fixation tests may be performed These are carried out with antigens prepared from alcohol extracted amebae according to Craig (1942) More recently the alcoholic antigen of Rees (1942) has become commercially available The method of Bozicevich Hoyem and Walston (1946) (Gradwohl 1948) is recommended

The complement fixation test is most valuable in amebic liver disease It becomes negative after the disappearance of the amebae

Blood Picture

There is no blood picture characteristic of amebiasis A microcytic anemia is frequently seen *The red blood cell count is between* 4 000 000 and 5 000 000 the hemoglobin is 65 to 80 per cent, sometimes higher

In acute stages the white blood cell count is higher than in bacillary dysentery In chronic cases without complications it is below 12 000 The lymphocytes may be increased and a slight monocytosis may exist An increase in the number of the eosinophiles is observed only in some patients

PROGNOSIS

If all types of amebiasis are considered the disease appears as a relatively mild illness with little mortality When clinically manifest cases alone are taken into consideration the mortality will be between 2 and 4 per cent This varies however with the locality and intensity of the disease While amebiasis in North America is generally mild during the severe Chicago out

break in 1933 the mortality reached 7 per cent About 40 per cent of patients with amebic typhlitis and appendicitis die when operated upon

Abscess formation makes the prognosis serious When a liver abscess perforates into the lung the prognosis is still somewhat better than if perito neal perforation occurs Brain abscess intestinal perforations and fulminant gangrenous cases of amebic dysentery are nearly always fatal

TREATMENT

Treatment of intestinal amebiasis consists of four factors antiprotozoan dietary supportive and symptomatic All of these are of great importance and must be carried out systematically During and after the course of ther apy one must bear in mind that only in a fraction of the clinically manifest cases is the treatment finished when the stools are free from amebae Many patients will require some special attention because of secondary infection and sequelae Careful analysis of the clinical sigmoidoscopic and x ray findings as well as stool studies will help to ascertain the best method for eradication of the residual troubles Excellent discussions of the antiamebic drugs have been published recently by Manson Bahr (1943) Craig (1944) Klatskin (1946a) Karl and Sloan (1946) Raul (1947) Arnett (1947) and others

Antiamebic Drugs

Emetine —This is the oldest and most highly valued drug Experience however has shown that emetine does not kill the amebae but simply allevi ates the toxic symptoms On the other hand this drug in itself is very toxic Acting directly upon muscle fibers it causes true myositis The heart muscle suffers most frequently (Dack and Moloshok 1947) The first signs of emetine intoxication are usually a drop in the blood pressure and irregular heart action Tachycardia is often present The patient is weak and may complain of paresthesias Diarrhea is not rare Symptom complexes re sembling neuritis have been described Progressive muscular atrophy and trophic disturbances of the skin of the hair and of the nails have also been observed Children and pregnant women are very sensitive to this drug therefore it should not be prescribed for them Manson Bahr (1943) called attention to the fact that amebae may become emetine resistant if the drug is not used wisely

In order to carry out the treatment in the most proper manner the pa tient must remain in bed during the course of treatment and for three days following it Blood pressure and pulse rate must be watched carefully The treatment must be discontinued immediately if the blood pressure drops, the pulse frequently increases or other signs of emetine intoxication appear

Oral emetine treatment is new in America (Shrapnel et al 1946) Em etine by mouth causes emesis and is less effective Intramuscular injections are preferred by many authors Some writers warn against the subcutaneous route because of the possible sensitivity of the skin The drug must never be given per rectum or into the veins

*See also Chapters 65 and 66

The daily dose is 0 06 Gm best divided into two portions 0 03 Gm in the morning and the same amount in the evening The duration of the treatment is six to seven days never longer than eight to ten days If the emetine helps it causes cessation or partial relief of the symptoms within the first four days There is little use in continuing the drug on or after the fifth day if the condition of the patient has not improved

A second course of emetine should not be given until at least three months have elapsed since the first course of treatment with emetine Longer courses are advocated by Klatskin (1946 and 1946a)

Emetine is the only known drug which acts upon amebic tissue (Parmer 1948) In spite of its toxic action it must be used Indications for emetine treatment are

1 Amebic dysentery
2 Acute or subacute amebic typhlitis and appendicitis
3 Amebic hepatitis
4 Amebic abscess

Contraindications of emetine therapy are

1 Children
2 Pregnant women
3 Emaciated cachectic patients
4 Cardiac disturbances including sclerosis
5 Forms of amebiasis not listed as indications for emetine therapy

Emetine bismuth iodide contains 25 to 30 per cent emetine It is given by mouth in gelatin or salol coated pills It is best used according to the principle of Manson Bahr (1943) which with some changes is given below

The patient is put to bed for the duration of the treatment and for three additional days Fasting for three to four hours before the pill is taken is essential The drug is given late in the evening The treatment lasts for ten to twelve days during which period the patient receives a total of 1 65 to 2 Gm of the drug 0 05 Gm the first two days 0 1 Gm the next two days and then 0 2 Gm per day are given together with a light sedative

The indications and contraindications for this treatment are in our opinion the same as for emetine injections The patient is observed as when emetine is injected Vomiting is a very unpleasant *effect of emetine-bismuth* iodide often forcing discontinuation of this medication

Derivatives of Arsonic Acid —*Carbarsone* Amebarson p carbamino phenylarsonic acid with about 28 per cent As is given in gelatin *capsules* containing 0 25 Gm of the drug two capsules a day for ten days It is also available in tablets

Carbarsone in powder form may be used for enemas After a cleansing enema 200 c c of a warm 2 per cent solution of sodium bicarbonate and 1 per cent carbarsone are introduced The patient must retain this enema for at least three to four hours This is easily accomplished when the patient lies in bed and is allowed to change his position every hour A mild sedative may be given

Children receive 0 025 Gm carbarsone per year of physical age every day The treatment lasts for ten days

Acetarsone Stovarsol Kubarsol Spirocid Fourneau 270 3 acetylamino-hydroxy phenylarsonic acid containing about 27 per cent As, is used in the same dosage as carbarsone It is, however absorbed from the intestine

Both drugs are toxic for the liver and kidneys They may cause symptoms of arsenic intoxication such as colic diarrhea and dermatitis

According to Craig (1944) arsenic preparations should be reserved for cases in which iodine preparations (and if indicated also emetine) have proved unsuccessful The author suggests the use of carbarsone mainly in children who cannot receive emetine and in combination with other drugs

Neoarsphenamine was tried by Bruce (1946) *Vilibis* has little effect

Iodine Preparations—*Chiniofon* Quinoxyl Kubalen, Anayodin, is a mixture of 4 parts of 7 iodo 8 hydroxyquinoline 5 sulfonic acid or its sodium salt containing 28 to 29 per cent iodine and 1 part sodium carbonate

Chiniofon is an excellent antiamebic drug Sometimes it causes diarrhea which is often stopped by bed rest and strict diet Manson Bahr (1943) recommends that this drug be given with small amounts of opium for example 0 03 Gm t i d Craig (1944) had excellent results with chiniofon

Chiniofon is available in pills or tablets containing 0 25 Gm There seems to be disagreement concerning the dosage of this drug A course of 3 to tablets a day after meals for seven to ten days is recommended After one week interval the treatment may be repeated Others prescribe one pill t i d the first day two pills t i d the second to the fifth day and three pills t i d on the sixth and seventh days Then for three weeks two pills t i d are given every Friday Saturday and Sunday

Children receive one tablet for each five years of physical age every day for a period of ten days

For rectal application 200 c c of a 2 to 3 per cent solution are given after a cleansing enema It is recommended that the patient follow the same precautions as in rectal therapy with carbarsone The enemas are repeated every day for five to ten days

Vioform Enterovioform Protozida is iodo chloro hydroxyquinoline with 37 5 to 41 5 per cent iodine It is a much used drug It may cause irritation of the gastrointestinal tract mainly of the stomach It cannot be given per rectum

Vioform is available in pills tablets or gelatin capsules with 0 25 Gm of the drug Adults receive one to two tablets t i d after meals for ten days After an interval of one week the course may be repeated Children take one tablet per day for each five years of physical age for the period of ten days

Diodoquin diiodohydroxyquinoline contains 63 9 per cent iodine It causes very few secondary effects This was emphasized by D Antoni (1942)

In the author's experience only one case of iodism and two cases of irritation of the bowel occurred among more than 430 patients On the other hand, approximately 76 *per cent* were cured

Adults receive 2 to 3 tablets t i d *after meals for twenty days.* After a one week interval the treatment may be repeated Children receive 2 tablets a day for each five years of physical age for ten days

Diodoquin is the oral drug of choice but is not given per rectum

Combined Treatment—Manson Bahr (1943) gives emetine bismuth iodide by *mouth* and chiniofon in enemas for ten days This treatment requires sedation to be given *during the course* Of 535 cases of amebic diarrhea and dysentery only 1 4 per cent showed relapses after this treatment

Craig (1944) suggested that amebiasis be treated according to the type of the disease He recommends emetine and chiniofon in amebic dysentery and chiniofon or Diodoquin in other types If these drugs do not act in a satisfactory way Carbarsone is given The dosage of the drugs is regulated by the *severity of the disease*

For a combined Protozida and Kubarsol treatment Amebo Oral "Kuba" is used Adults receive 4 to 8 tablets a day and children 1 tablet for each five years of physical age a day

Browne et al (1945) concluded that differences in various schedules of treatment are unimportant

We feel that each drug has its own field of indications and contraindications The choice of an iodine preparation may be difficult One should keep in mind that if one of them is not tolerated or does not act another may be used with success We use Diodoquin in moderate cases and for children Chiniofon is indicated in severe conditions since it may be given *rectally* Carbarsone is used more than Acetarsone *Table IV shows our schedule of treatment*

Other Drugs—*Bismuth subnitrate* was widely used before more effective drugs were devised Now it is restricted to the treatment of postamebic diarrhea

Kaolin bolus alba in large doses as much as 50 to 100 Gm a day as an intestinal absorbent is often given *It may however also absorb the antiamebic drug which is administered Therefore it is preferably used between* periods of active antiprotozoan treatment

Antimalarial drugs as Aralen and Pentaquine, have recently been used alone or in combinations

Kurchi bark from *Holarrhena antidysenterica,* used as kurchine hydrochloride 0 03 Gm to 0 06 Gm subcutaneously or as kurchine bismuthiodide 0 3 Gm by mouth has a questionable curative effect

Chaparro amargoso is derived from *Castela nicholsoni* an American plant Its bark and leaves are used in decoctions and infusions The dosage is 3 teaspoonfuls a day for ten days or enema of 250 to 500 c c *Comprehensive* statistics on the action *of this drug* are *still* lacking

Sulfonamides are beneficial in heavy secondary infections Especially sulfadiazine is recommended by Karl and Sloan (1946)

TABLE IV TREATMENT OF AMEBIASIS

TYPE OF AMEBIASIS	FIRST TREATMENT	CONTRAINDICATIONS	INTERMISSION	IF UNSUCCESSFUL, TREATED WITH	CONTRAINDICATION	SECOND TREATMENT IF NECESSARY
Subclinical and patients with constipational type	Diodoquin, 2 3 tablets t i d for 20 days	None	10 days	Carbarsone, 1 tablet b i d for 10 days	Liver and kidney disease	Repeat Diodoquin or chiniofon, 2 3 tablets t i d for 10 days
Amebic diarrhea intermediate forms syndromic amebiasis without toxicity	Diodoquin, 2 3 tablets t i d for 20 days	None	1 2 days	Carbarsone 1 tablet b i d for 10 days, and chiniofon enemas, 2 5 Gm for 5 to 10 days	Liver and kidney disease	Repeat Diodoquin, or if unsuccessful in first course, chiniofon 2 3 tablets t i d for 10 days
Toxic amebiasis, amebic dysentery	Either emetine injection, 0 03 Gm b i d for 5 7 days, or emetine per os always with chiniofon per rectum for 5 10 days	Heart disease	1 2 days	Carbarsone, 1 tablet b i d or enemas for 10 days if not tolerated Diodoquin 2 3 tablets t i d for 10 days to 20 days	Liver and kidney disease	Vioform, 1 2 tablets t i d for 10 days, repeat after 7 days intermission
		Severe liver or kidney damage			None	
Amebic hepatitis and other extraintestinal forms	Emetine injection, 0 02 Gm b i d for 5 10 days	Heart disease	1 2 days	Revise diagnosis Aralen 0 25 Gm t i d for 10 14 days	None	Treat amebic intestine (penicillin, sulfonamides)
Amebic abscess	Emetine injection, 0 03 Gm b i d for 5 10 days and puncture	Heart disease	According to case	Surgery	Severe cachexia	Penicillin, sulfonamides
Fulminating amebiasis	Emetine injection 0 03 Gm b i d for 5 to 10 days	Heart disease	0	Chiniofon enemas for 10 days		Penicillin, sulfonamides
	Penicillin G 300,000 U	None				
	Bacitracin 120 000 U daily	None				

Emetine, penicillin, and *sulfonamides* are combined by Blanc and Siguir (*1946*) and Klatskin (1946), especially for acute cases and liver complications

While this book has been in press, the following antibiotics have been found effective in amebiasis aureomycin 2 Gm *per day for ten days*, bacitracin 60,000 to 150,000 U per day for ten days Neomycin 100,000 U daily per os, eventually combined with bacitracin Chloromycetin 2 Gm per day for ten to fourteen days

Dietary Treatment

While diet must not be restricted unduly and enough should be given to support life adequately, it is dangerous to neglect the diet D'Antoni (1942) first described a practical diet to be followed in dysentery that takes into account the food habits of the Americas and that can be easily carried out This diet was originally devised for the treatment of bacillary dysentery We have recommended it in more than 800 cases of both chronic protozoan and bacillary dysentery With a few adjustments for the requirements of the amebic patients, we recomend the diet as follows

Permitted All types of bread, preferably toasted, crackers, breakfast cereals, lean and well done beef, lamb, fowl, rabbit, game, veal liver and tongue, puréed cooked vegetables such as beets, eggplant, spinach, tomatoes, green peas, lettuce, cauliflower, Irish potatoes, rice, sago, cooked prunes, apples, baked apples, pure cream and noodle soups, salt, *macaroni, spaghetti, vermicelli* noodles

Restricted 1 or 2 cookies or biscuits a day, once a week, milk pudding, bacon, brain, lean pork, once or twice a week, boiled, baked, or fried trout, pike, red fish or haddock, juices of tomatoes and vegetables, once or twice a week, *prune or pineapple juice raw tomatoes and alligator pear, puréed* carrots, artichokes, string beans, asparagus, raw or stewed pears, apples, bananas, peaches, cottage cheese, American and Swiss cheese, scrambled or poached eggs, 4 a week, one glass of milk a day, or less, one cup of coffee or one to two cups of cocoa a day, tea, vegetable fats, smoking

Not permitted cakes doughnuts, pies syrup chocolate, *Jello, candies*, veal, with the exception of liver and tongue, fat meats hamburgers, sausages, salami, kidneys, corned, dried, or cured meats, sardines anchovies, and fish not listed as "permitted", vegetables and fruits not listed as "permitted", greasy soups, sauces, pepper, paprika, vinegar, carbonated and alcoholic beverages, *root beer, ginger ale, chili* sauce ketchup honey, nuts, pickles, spices

This diet is empirical Carbohydrates and vegetables with strong fibers are restricted in it, as well as irritating food Milk and milk products, which are frequently the source of abdominal discomfort in gastrointestinal disturbances and *often* cause allergic phenomena, are practically eliminated The diet is easily tolerated The restriction of sweets, ice cream, candy, and carbonated beverages is often resented by young people, particularly in summer We found that it is better to add to the *diet orange, pineapple and* grape juice, strongly diluted with water, than to forbid all beverages and have

the young patient consume sodas and sundaes topped with carbonated drinks Weak tea hot or iced with flavor if desired and Postum may be used to quench thirst and aid in the maintenance of a high fluid intake an important point in dealing with progressive diarrhea

Patients in acute stages are put on a high caloric low residual diet At least twice a day some chopped well done beef and beef broth or chicken soup must be given with boiled potatoes or well cooked rice Once a day puréed tomatoes beets eggplant spinach or okra are served Small pieces of white toast with butter supplement the meals Weak tea and weak cocoa without milk tomato and prune juice diluted orange and pineapple juice are given During this acute stage the food must be given every two to three hours in small portions

It is essential that a patient with acute dysentery remain in bed

Supportive Treatment

Every case of clinically manifest amebiasis needs supportive treatment with liver and vitamins Because of the impaired intestinal absorption of vitamins only parenteral administration is really effective Intramuscular injections are preferred In the beginning three and later two injections per week are recommended Each injection consists of 3 to 5 c c of crude liver extract and at least 5 mg thiamine hydrochloride and 75 mg ascorbic acid According to the condition of the patient the injections are continued for two to three months and then the series is repeated eventually with only one injection *a week* Folic acid 5 to 20 mg per day is very beneficial

Symptomatic Treatment

Postamebic diarrhea and flatulence usually subside under the following treatment

Kaolin	0 3 Gm
Magn oxide	0 2 Gm
M f p D t d No 20	
S 1 powder t i d p c	

Commercial combinations of kaolin and magnesium or of kaolin and pectin are also useful

Spasm and pain in the abdomen promptly react to

Papaverini hydrochlor	0 4 Gm
Novatropini sulphur	0 00 3 G
Acid. phenylethylbarbit	0 2 Gm
Sacchari	5 0 Gm
Div in dos No 20	
S 1 powder t i d	

Synthetic drugs acting like papaverine (Pavatrine) are also useful

Constipation may be treated with paraffin oil sodium or magnesium sulfate One to three teaspoonfuls of the sulfates are given in some water before breakfast Sodium phosphate is also effective

If the diarrhea does not disappear and the stools do not contain pathogenic organisms Manson Bahr's prescription (1943) is very helpful

Tannic acid	10 0 Gm
Quinine hydrochlor	1 0 Gm
Warm water	2 L
M D S Enema	

When secondary infection with proteolytic organisms is present sodium sulfaphthalidin 3 to 6 Gm a day for five to ten days may be used Sulfadiazine is given as in bacillary dysentery

Enemas with 1 500 to 1 1 000 Rivanol are also effective

Treatment of Complications and Sequelae

Amebic Liver Disease—Strict bed rest is indicated and emetine is injected Hot packings applied without pressure alleviate the pain

If an abscess of the liver is diagnosed aspiration is performed This is carried out in an operating room so that more extensive surgery can be performed immediately if need arises during the puncture Either a special puncture needle or that routinely employed for lumbar puncture is used Some workers prefer full sized aspiration needles It is advantageous to use an aspirator

Local anesthesia is given In sensitive patients general narcosis must be applied The puncture is performed in the direction of the most prominent portion of the liver upward inward Only abscesses of the right lobe are accessible for aspiration The needle must not be introduced deeper than 10 cm to avoid large vessels The pus is chocolate brown or red and thick with pieces of necrotic tissue Yellow or green pus signifies secondary infection The pus aspirated at the first puncture does not contain amebae When the pus becomes thinner in the course of repeated aspirations amebae may appear

After aspiration 100 000 units of penicillin are injected into the cavity The patient receives 200 000 units of penicillin and some soluble sulfonamide drug for example sulfadiazine on the days when aspirations are performed The injection of 10 c c of Lipiodol and 100 000 units of penicillin into the abscess cavity is very beneficial Penicillin G is preferred

Surgical operation is indicated when (1) inaccessible or multiple abscesses are present (2) hemorrhages occur, (3) there is a secondary infection which resists treatment with antibiotics and sulfonamide drugs (4) the abscess does not show a tendency toward healing, (5) fever persists (6) perforation of the abscess occurs

Before operation penicillin and sulfonamide drugs are given When gram negative rods are present in the pus, streptomycin must be used Usually either the transperitoneal or the transpleural route is used followed by drainage Adequate use of antibiotics and sulfonamide drugs reduce the operation hazards

Intestinal Perforation—While operation on a nonperforated amebic intestine is contraindicated, it is imperative to attempt surgical correction of a perforated bowel. Extensive resection is the method of choice. In dealing with a perforated amebic appendicitis, make drainage through a small surgical incision. The prognosis is always very serious.

Bleeding—Manson-Bahr (1943) recommends cecostomy, when the usual styptics and lavages do not control the bleeding. After the operation lavages with styptics are carried out through the artificial anus. Transfusions of whole blood and plasma, 300 to 500 c c for adults are beneficial.

Malformations of the Colon—Excision of the diseased parts is recommended if strictures or stenosis have developed. If there is no danger to life, one should wait with such an operation until the amebae disappear from the stool.

PROPHYLAXIS

Craig (1944) recommended 1 to 3 tablets of chiniofon a day while sojourning in a heavily infested locality.

General hygienic measurements are essential: (1) survey of the population, principally of food handlers and food workers, (2) treatment of all infected persons, (3) adequate food and water control. If these measures are impractical: (1) drink only boiled water and (2) eat only adequately boiled food served by clean food handlers.

AMEBIASIS CAUSED BY OTHER AMEBAE

The amebae usually found in the human intestines are *Endamoeba histolytica*, *Endamoeba coli*, *Endolimax nana*, *Iodamoeba butschlii*,* and *Dientamoeba fragilis*. There is no doubt concerning the pathogenic power of *E histolytica*. Many authors, however, believe that only this ameba is able to cause amebiasis. A few observers have described pathologic conditions in which other amebae have played an important role. In the most recent literature, Derrick (1945) and Kaufman (1945) reported amebiasis due to *I butschlii*. Some advocate that *D fragilis* is definitely pathogenic, for example, Halawani (1933), as is proved also by the x ray findings of Arendt and Cohen (1948).

PATHOLOGY

Amebae other than *E histolytica* do not produce lesions similar to those found in amebic dysentery, as seen at autopsy. Tissue invasion, however, has been noted at autopsy.

CLINICAL SYMPTOMS

In patients diagnosed by us as having iodamebiasis or dientamebiasis, vague pains in the abdomen and "mushy" stool, rarely true diarrhea lasting a few days were present. Most of the patients were children. In adults constipation interrupted by diarrhea was the rule. Abdominal distention and borborygmus were common. One case of dientamebiasis resembled chronic appendicitis. The stools very often contained mucus. Blood was never found.

LABORATORY FINDINGS

The stools contained undigested food, only a few epithelial cells and, rarely, a few leucocytes. The amebae were numerous. Because of the quick disintegration of both species of amebae in the stools, the examination must be carried out with even greater haste than for *E histolytica*. We found hematoxylin stained slides indispensable for the diagnosis of these

**Iodamoeba williamsi.*

amebiae The use of a higher per cent strength of acetic acid, 10 to 20, is often recommended to afford better preservation of the structures of *I butschlii* and *D fragilis* The procedure described in Chapter 71, however, gives satisfactory results in most cases

No significant changes in the blood picture were observed A microcytic anemia existed in the chronic cases

TREATMENT

Diodoquin, 2 to 3 tablets t i d for twenty days, rendered excellent service Children were given 1 tablet a day for each five years of physical age for the same period The diet was adjusted as for amebiasis caused by *E histolytica*

GIARDIASIS

Giardiasis is a disease of world wide distribution, caused by *Giardia lamblia*, a flagellated protozoan

PATHOLOGY

No satisfactory autopsy reports are available The x ray findings of Welch (1944) show functional rather than anatomic changes It is theorized that Giardiae irritate the mucosa and cause disturbances in the motor activity The organism is most frequently found in the duodenum and often invades the gall bladder

CLINICAL SYMPTOMS

Brown (1945) called attention to the fact that children show more symptoms than adults The complaints consist of abdominal distention, feeling of pressure, and dull pain usually under the right ribs, increasing between meals The pain often is not localized so precisely It may migrate into the area under the xiphoid process of the sternum or other areas Even short colics may be observed Manson Bahr (1943) distinguished acute and chronic recurrent giardiasis In the latter type, constipation may alternate with diarrhea

The number of stools in the diarrheal period is two to ten, usually three to five a day They are liquid, later semisolid or solid containing mucous but no blood They may be sprue like The odor is often very offensive

While about 3 to 18 per cent of the population of the Americas harbor Giardia, according to the geographic position, only a few of the infected persons show clinical symptoms, therefore, a subclinical type of giardiasis must be accepted.

The clinical picture often resembles that of duodenal ulcer or chronic enterocolitis The differentiation is easy with the aid of the laboratory

LABORATORY FINDINGS

Motile trophozoites are more frequent in liquid stools and in gall bladder contents Formed stools usually contain cysts, which are found with relative ease Children often show microcytic anemia

TREATMENT

Brumpt (1937) introduced Atabrine in the treatment of giardiasis This drug is best given 0 1 Gm t i d for seven days Children over 10 years receive 0 1 Gm b i d for five days Because of its toxicity in small children, Atabrine must be replaced by carbarsone or iodine preparations, in the same doses as in the treatment of amebiasis

COCCIDIOSIS

This is a very rare infection in human beings, caused by *Isospora hominis*, a parasitic sporozoan Kiskaddon and Renshaw (1945) collected 213 cases from the literature Consentino (1945) described one in Brazil, Beltrán (1943) in Mexico, and Humphrey (1946) in the United States

PATHOLOGY

The organism does not invade human tissue No autopsy reports are available

CLINICAL SYMPTOMS

In the two cases which we observed, only mild diarrhea was present without pus or blood but with much mucus in the stools The feces were light colored and liquid and had an offensive odor There were no general complaints Both patients recovered within five days

LABORATORY EXAMINATION

Characteristic spores are found in the stools which contain undigested food some epithelial cells and mucus Many authors have described Charcot Leyden crystals in the feces

TREATMENT

The disease is self limited No therapy is necessary

BALANTIDIASIS

Balantidiasis designates invasion of the intestines by *Balantidium coli* a ciliated protozoan

AGENT

The disease is transferred from pig to man or from man to man by contaminated food or water Also farmers handling infected animals and butchers or abattoir employees become infected The infective form is the cyst which is very resistant to outside agents The cysts are able to survive in feces and in water for weeks but are easily destroyed by sunshine

PATHOLOGY

The findings are similar to those in amebiasis The organisms penetrate between the cells of the columnar epithelium and the Lieberkuhn cysts and descend to the basement membrane of the mucosa If bacteria do not accompany the balantidia no inflammatory reaction is observed in this stage Later cytolysis with consequent suppuration develops The balantidia are found also in tissue without reaction or with little reaction They may show degenerative changes which begin with karyorrhexis The areas of suppuration are later surrounded by fibrosis

After the necrotic tissue debris becomes detached from the intestines irregular ulcers with undermined edges are seen The mucosa between the ulcers is intact except for occasional small hemorrhages Secondary infection may alter the picture If the ulcers heal fibrotic scars are formed

CLINICAL SYMPTOMS

Recently Jaffe and Kann (1943) described balantidiasis as occurring frequently in Venezuela Beltran (1942) found fifty nine cases in Mexico Tsuchiya and Kenamore (1945) reported on balantidiasis in the United States

The clinical symptoms are the same as in amebiasis Invasion of the intestines by balantidia may be symptomless as in the case observed by us If clinical signs of disease are present, they vary from uncertain, vague ab-

Fig 23 —Base of balantidial ulcer (Original photomicrograph of Oscar Felsenfeld)

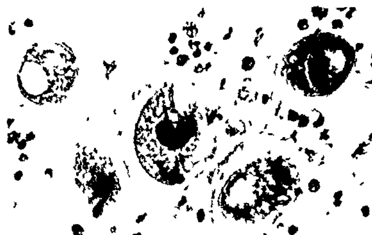

Fig 24 —Degenerating balantidia in the *intestine* (Original photomicrograph of Oscar Felsenfeld)

dominal discomfort to acute dysentery Pain and tenderness may be localized over the cecum There is *either constipation alternating* with diarrhea, or a chronic diarrhea, with three to fifteen stools a day, which are semifluid or

fluid and light colored or greenish and have an offensive odor While mucus is regularly found, blood appears only in acute cases The disease cannot be differentiated from amebiasis without stool examination

LABORATORY FINDINGS

The stool contains many balantidia in the beginning, but few leucocytes Later the number of balantidia decreases and the number of leucocytes increases Mucus is almost always present Charcot Leyden crystals may be present In uncomplicated cases the blood picture is essentially normal

TREATMENT

Carbarsone, 0 25 Gm b i d , for ten days and chiniofon in large doses, 3 tablets t i d , for seven days are recommended

The prognosis of balantidiasis is favorable except in emaciated patients

Microfilariae in the Suspected Onchocercoma—The onchocercoma should be punctured the contents aspirated and then immediately examined on a slide with a cover glass It is possible to find numerous microfilariae but it is also possible that the investigation will give negative results if only adult parasites are present or if the adult parasites are of the same sex or if they are dead

Discovery of Microfilariae in the Eye—With the biomicroscope it is possible to see the microfilariae in the anterior chamber of the eye They appear as *very minute thread like bodies thin and refractive moving incessantly* and frequently escaping from the field of observation

Pathologic Findings in the Lesions—Pathologic findings in the lesions are so valuable that alone they are able to confirm the diagnosis

Peripheral Blood—There is usually a marked eosinophilia present

Fig 286—The author's technic of pressure by forceps and piercing with needle

Other Findings.—The complement fixation reactions of Gutierrez Villegas (1931) and others the cutaneous allergic reactions discussed by Hoffmann *and Vargas (1931) Mazzotti and Osorio (1943) and Wright and Murdock* (1944) the investigation for microfilariae in the spinal fluid and the erythrocytic sedimentation test of Linzenmeier have not proved to be of value in the diagnosis of onchocerciasis

PROGNOSIS

Onchocerciasis is not a fatal disease Its seriousness consists of the possibility of blindness from atrophy of the eyeball or of a secondary glaucoma However the regular surgical removal of the onchocercoma as well as careful search of the substances which elude ordinary exploration and future removal of them has reduced the number of onchocercal patients

Plasmodium Vivax (Grassi and Feletti 1890)

These parasites in the initial stages are tiny organisms, usually containing a chromatin granule In most cases only one parasite can be found in each parasitized red cell although at times there may be more—occasionally as

Fig 26—Stomach of the mosquito with oöcysts of *Plasmodium vivax* Delafield hematoxylin stain. (×3 000) (Original photomicrograph of L. Beltrán.)

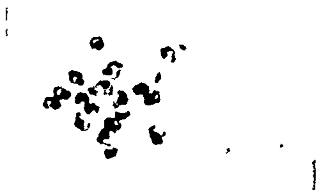

Fig 27—Merozoites of *Plasmodium vivax* Giemsa stain (×3 000) (Original photograph of L. Beltrán)

many as six in one erythrocyte The parasite soon begins to grow assuming an irregular ameboid shape and moves rapidly within the cellular stroma The name *vivax* is given to this species because of the vivacity of its move

CHAPTER 5

PLASMODIA OF MAN AND ANIMALS

ENRIQUE BELTRÁN

HISTORY

In 1880 Laveran, in Algiers, found in the blood of patients with malaria parasites which he considered to be the cause of the disease and which today are included in the order Haemosporidia, of the class Sporozoa, in the genus *Plasmodium*

Almost simultaneously with Laveran, Danilewski (1885), a Russian investigator, found in the blood of birds parasites that were very similar to those discovered by the French investigator, some of which today are considered as belonging to this same genus Plasmodium

Koch (1898) shortly afterward found similar parasites in the blood of monkeys

Last, Wenyon in 1908 (1926) and Aragao and Neiva (1909), independently in the same year, 1908 1909, found that reptiles also could be parasitized by Plasmodia

It is now known that parasites of the genus *Plasmodium* exist in various vertebrates, including mammals, birds, and reptiles

PLASMODIA OF MAN

Although Laveran had noted the entire asexual cycle of the parasite, it remained for Golgi (1889) to describe the different stages, thus establishing its relationship to the clinical manifestations of the disease

Due to the work of Ross (1895, 1898) in India and of Grassi, Bignami, and Bastianelli (1899) in Italy, it was soon established that the anopheline mosquitoes transmit this disease to human beings

The species generally accepted at present are
Plasmodium vivax (Grassi and Feletti, 1890),
Plasmodium malariae (Grassi and Feletti, 1890),
Plasmodium falciparum (Welch, 1897),
Plasmodium ovale (Stephens, 1922)

There is also lack of agreement concerning the proper designation of the genera and species of plasmodia which are found in man The problem is still under discussion (Coatney and Young, 1941, Sabrosky and Usinger, 1944, Beltrán, 1944) The designations given above have been accepted, according to International Rules on Zoological Nomenclature.

These plasmodia require two hosts One phase, the asexual, occurs in human blood, while the second phase, the sexual, takes place in the mosquito The four species present such marked uniformity in their life cycles that we can describe this cycle in general terms.

Infection in man begins with inoculation of sporozoites from the saliva of an infected mosquito For a long time the statement of Schaudinn (1903) was accepted that the sporozoite, after inoculation into the blood, penetrated directly into an erythrocyte, there it assumed the form that is typical of young trophozoites Schaudinn's observations could not be confirmed by other authors Moreover, it was proved that, from the time of inoculation by the mosquito to the first appearance of the forms which attack the red cells, there is a period during which no parasites can be observed microscopically and that the blood is not infective when inoculated experimentally into susceptible subjects

Fig 29—*Plasmodium falciparum*, blood smear Giemsa stain. *1*, young trophozoite [illegible]

Fig 30—*Plasmodium ovale*, growing schizont (Original photomicrograph of O Felsenfeld

ments When it attains its full growth there appear within it golden colored granules, these are spherical or rod shaped bodies These bodies are at first distributed uniformly throughout the parasite later they tend to become grouped into one central mass

Characteristic of this species is the increase in size of the parasitized red cells the cytoplasm becoming filled with dark red granulations These are called *Schuffner dots* They are considered one of the important diagnostic characteristics of this species

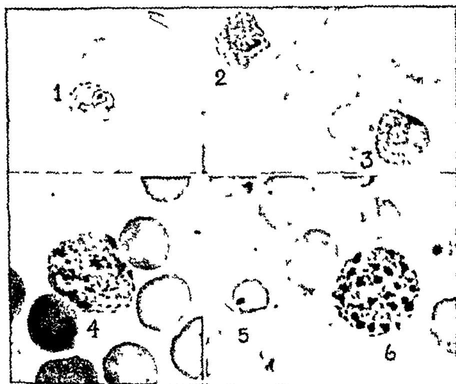

Fig 28 — [illegible] with Schüffner [illegible] young ring [illegible] with numerous [illegible] parasites note [illegible] *Hasnuevo* in *Le*[illegible] Medical Protozoology)

The trophozoite develops into a schizont and then into the segmented form usually with twelve to twenty four merozoites In Mexican strains of parasites (Beltran and Villasana 1945) the average number of merozoites is fourteen to sixteen

The schizogonous cycle of this species usually requires about forty eight hours a fact which explains the febrile attacks every third day However in double infections or because of lack of synchronization of one of the generations of the parasites there often can be observed a daily febrile reaction

The gametocytes are *round, but small, and of darker color, especially the macrogametocytes which are stained an intense blue*

The asexual cycle of this species usually requires seventy two hours which explains the periodicity of this type of intermittent fever, called *quartan fever*

Plasmodium Falciparum (Welch, 1897)

With *some exceptions, young forms alone are found in the peripheral* blood, these correspond to the ring forms or to young trophozoites At times *as many as six ring forms of the parasite may be found in a single erythro* cyte The schizonts *and segmented forms are localized in the visceral* circula tion The rings are usually smaller than those of the other two species, they frequently have two chromatin granules and are found in normal sized eryth rocytes, usually near the periphery

TABLE VI MORPHOLOGY OF PARASITES IN THICK BLOOD FILMS
(Courtesy of J W Colvin)

	Forms Present
Plasmodium vivax	All stages of development
Plasmodium malariae	All stages of development
Plasmodium falciparum	Only rings or rings and crescents

The Young Trophozoites (Least Diagnostic)

Growing and Large Trophozoites

P vivax—Abundant masses and blobs of light blue cytoplasm connected by threads or not visibly connected arranged in "Y" forms or triangles ameboid activity re flected older forms with fine yellow brown pigment, irregular, chromatin round or irregular

P malariae—Single blob of deep staining cytoplasm compact and close to nucleus, usually rounded or band forms, older forms chromatin may be obscured by crowding cytoplasm or elongated, heavily pigmented dark brown to black coarse granules

P falciparum—*Very much like young vivax* possibly more compact may still show double dot forms occasionally pigmented

Schizonts

P vivax—Chromatin masses irregular in contour in immature forms, 12 or more nuclei *in older forms* pigmented clumps

P malariae—Pigment more abundant 12 or less nuclei in *older forms, characteristic* arrangement in "rosette" or "daisy" pattern

P falciparum—Rarely seen, small both in size of parasite and size of nuclei, pigment dark to black

Gametocytes have a crescent shaped form with the nucleus and pigment near the center *The peculiarity of shape of the gametocyte distinguishes this* species from *others found in man*

The time required to complete the asexual cycle or schizogony is ap proximately forty eight hours as with *P vivax*, but there is generally marked

A characteristic of this species is observed in the merozoites which show marked preference for young erythrocytes or reticulocytes a phenomenon first noted by Craig in 1920 We have been able to verify this (Beltran 1941 Beltran and Sandoval 1945)

Gametocytes are round and relatively large and are easily identified by the enlargement of the erythrocytes in which they are found The gametocytes take a more delicate color than do those of *Plasmodium malariae*

TABLE V MORPHOLOGY OF MALARIAL PARASITES IN THIN BLOOD FILMS
(Courtesy of J W Colvin)

	P VIVAX	P MALARIAE	P FALCIPARUM
Color of cytoplasm	Light blue	Deep blue	Blue
Color of pigment	Yellow to brown	Black	Brown to black
Young Trophozoites			
Form	Small and large rings	Small compact rings	Small, delicate rings
Chromatin	Usually one dot	Large single dot	Often double dots
Pigment	None	Absent or fine	None
Growing Trophozoites			
Form	Irregular contour	Oval or bands	Rings
Chromatin	A dot or thread	A dot or thread	Often double dots
Pigment	Fine granules	Coarse granules	Scanty granules
The Infected Blood Cell			
Appearance	*Enlarged, pale*	*Normal*	*Usually normal*
Stippling	Schüffner dots	None	Maurer dots
Multiple parasites	Common	Rare	Very common
Growing Schizonts			
Form	Irregular contour	Compact, oval or round	Rarely seen resemble *P malariae*
Chromatin	2 to 10 granules	2 to 6 granules	2 to 8 small clumps
Pigment	Fine granules or clumps	Coarse granules or clumps	Fine granules or a single mass
Mature Schizonts			
Merozoites	12 to 24 in two rings or irregular	6 to 12 single ring or cluster	8 to 32 in two rings or irregular small
Pigment	Excentric mass	Central mass	Single dark mass
Shape of Gametocytes	Round or slightly ovoid larger than the red cell	Round or slightly oval same size as red cell	Crescent or sausage shaped
Pigment of Gametocytes	Scattered	Clumped	Centralized

Plasmodium Malariae (Grassi and Feletti 1890)

The general appearance of the parasite in the various stages is similar to that of *P vivax* There are however marked differences

The ring forms are difficult to differentiate from those of *P vivax* The mature trophozoites frequently show elongated forms which extend across the erythrocyte as a band There is no alteration in the size of the parasitized red cell *The pigment is composed of dark irregular granules There are no* Schüffner dots In preparations of *P malariae* it is not rare to find some erythrocytes containing the so-called Ziemann stippling which are also reddish but with poorly defined outlines appearing only in few cells of normal size

The merozoites are somewhat larger than those of *P vivax* there are usually six to twelve of them formed the average being eight

pecies may be experimentally transmitted to the canary, *Serinus canarius* Those which are most extensively found and which have been used most frequently in the laboratory are *P cathemerium* *P relictum* and *P circumflexum* the canary being used generally as the experimental host

Wolfson (1938) inoculated the domestic duck with *P cathemerium* Later, *P lophurae* was also used in ducks and in chickens Brumpt's *P gallinaceum* (1935), a parasite of domestic poultry is very favorable for experimental study Versiani and Furtado Gomes (1941) found in Brazil a new species which infects the domestic hen, *P juxtanucleare* This species was found almost simultaneously by us in Huixtla, (Beltrán, 1941a)

FORMS RELATED TO PLASMODIA

There exist in man and in animals certain forms of parasites which in some ways may be considered related to the plasmodia

The genus Toxoplasma is relatively common in guinea pigs Some cases of toxoplasmosis have been reported in man especially in children

There are in birds intraerythrocytic parasites, related to Plasmodium, belonging to the genus Haemoproteus There also exists in birds a parasite of the white blood cells belonging to the genus Leucocytozoon

lack of synchronization of generations, with the result that the febrile reactions, which coincide with segmentation are irregular The number of merozoites is also quite variable, from eight to thirty six, with a tendency to the higher figures

Because of the morphologic and physiologic differences between this species and the other species of human plasmodia some authors believe that it should be placed in a distinct genus which they would call *Laverania* However, taking into acount the existence of intermediate forms in animal plasmodia most investigators do not follow this suggestion but prefer to retain *this parasite in the genus Plasmodium*

Plasmodium Ovale (Stephens 1922)

This is the rarest malarial parasite found in nature It is found in the Eastern Hemisphere cases have also been found in the Western Hemisphere The number of reported cases is still very small

The parasitized red blood cells are oval shaped (hence the name) contain many granules and take on a peculiar greenish hue In other respects the parasite follows the development of *P vivax* and *P malariae*

Fig 31 —Toxoplasma Smear from the brain of an infant. (Original photomicrograph of O Felsenfeld)

PLASMODIA OF ANIMALS

Plasmodia of mammals especially of the higher apes, have been used in the study of problems pertaining to pathologic anatomy and immunity in man Those most frequently used are *P knowlesi P inui* and *P kochi* found in Old World monkeys, and readily transmitted to *Macaca rhesus* the common laboratory monkey In the Western Hemisphere, *P brasilianum* a parasitic species found in the genus Alouatta has been used extensively

Plasmodia found in reptiles although they have been known for a long time, have aroused relatively little interest Thomson and Huff (1944), however, have again demonstrated the importance which reptilian plasmodia may have for chemotherapy and other research

The most important plasmodia found in animals and the most readily adaptable to experimental studies are those of birds As pointed out by Hewitt (1940) more than a dozen

CHAPTER 6

MALARIA

JOSEPH WESLEY COLVIN

Malaria (Italian colloquialism meaning "bad air") is a disease which is widespread throughout the world and endemic in a universal band bounded by latitudes of approximately 40 degrees north and 40 degrees south but epidemic far wider. It is produced by several species of the class Sporozoa in the phylum Protozoa and is characterized by its recurring periodic fever, debilitation and chronicity. Few diseases have had as extensive investigation as has malaria and writings concerning it extend back to Hippocrates and into lost antiquity. Certainly few diseases have touched its mark of cost to mankind. Malaria probably has a role in two million deaths annually and presents itself as a salient problem to medical minds each century. This in part is due to its prevalence, character and the elements involved in its transmission from man to mosquito to man. There are areas where strict vigil and earnest long untiring labor have been rewarded by the reduction or almost complete eradication of malaria as a health and economic problem. This has been done by breaking the links of the chain in the mechanics of its transmission.

CAUSATIVE AGENTS

The malarial parasites have been discussed in Chapter 5 and the description will not be repeated here.

Clinical observations of variations in species, virulence, infectivity and recurrences have led to the recognition of strains of plasmodia. These characteristics are apparently unrelated to the structural findings in the parasite.

Some strains under observation in the United States have been designated as follows (Coatney and Young 1941, Boyd 1945):

PLASMODIUM VIVAX	PLASMODIUM MALARIAE	PLASMODIUM FALCIPARUM

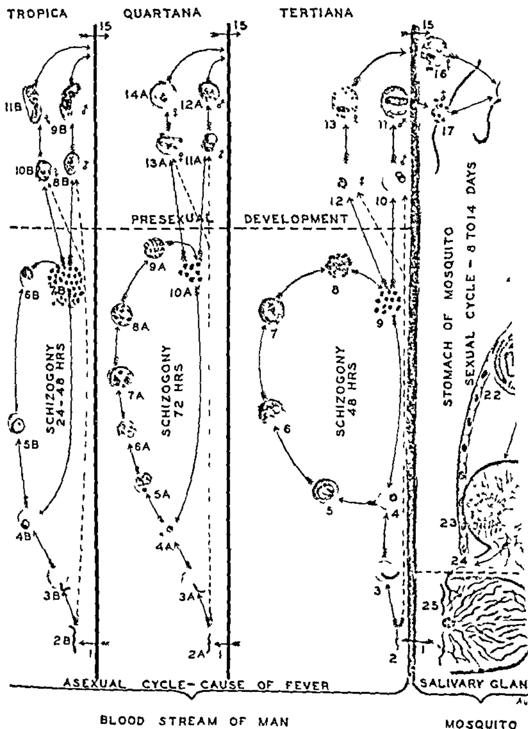
TABLE VII OBSERVATIONS ON TWO STRAINS OF VIVAX MALARIA
(From Swellengrebel and DeBeck 1938)

NAME	PARASITEMIA WITHOUT SYMPTOMS (%)	LATENCY PERIOD (DAYS)	DAILY FEVER (%)	HIGH FEVER (%)	SPONTANEOUS RECOVERY (%)	RELAPSES (%)
Holland	38	21	19	8	10	10
Madagascar	7	12	80	30	0	80

These are or have been used in the therapeutic induction of malaria for paretic patients Interesting racial resistance has been found especially in Negroes toward *vivax* infections Some workers have felt that Caucasians too in selected cases have exhibited a similar resistance James divides them into three groups very susceptible refractory and between these limits with a majority falling in the middle group In the treatment of paretic patients if one strain does not produce a malarial take a different strain is used Success is more likely to occur with a different species entirely though similar gradations of resistance have been reported in all species (James 1937 *vivax* and *falciparum* Sinton Hutton Shute 1939 with *ovale*) Boyd succeeded in inoculating 100 per cent of his patients on the second try with *P vivax* and felt that it was unsuccessful the first time because of parasitic alterations rather than the individual patients



VECTORS

See Chapter 7

PATHOLOGY

Malaria produces extensive physiologic and histologic changes accompanied by a multiplicity of significant pathology The reticuloendothelial system probably bears the brunt of the initial attack only to be taxed later with toxic by products and cellular debris during erythrocytic invasion The function and existence of red blood cells are destroyed by parasitism with a resulting state of toxicity whereby other nonparasitized normal erythrocytes may be destroyed by lysis The release of blood pigment from red cells in itself causes enough disturbance to disrupt hematopoietic balance to say little of other disruptions incident to protozoan infection Many events occur in pathologic sequence before onset of the varied anemic states induced by the increased destruction of red blood cells These are the poignant manifestations of the so called blood organs those with sinusoids liver spleen bone marrow etc Clark (1928) indicated that parasites have a tendency to localize in these places and pointed out that this might be a defense action on the part of the body This resultant centralizing of parasites causes retardation of blood passage and enlargement of the organs involved so that splenomegaly and hepatomegaly are features of the disease when fully developed in the host The pathologic response is one of hyperplasia hypertrophy and pigmentation

CYCLE OF DEVELOPMENT OF MALARIAL PARASITE IN MAN AND MOSQUITO

The white blood picture in malarious infections changes from one of normal tenure to one of reduced white blood count leucopenia. This is reversed somewhat during the paroxysms and then decreases. Persistent malarial latency found in *P vivax* and *malariae* usually brings about an increase in large mononuclear leucocytes. The picture is therefore one of leucopenia with a later absolute mononuclear leucocyte increase. The same in general applies to *P falciparum* infections this species is not as refractory to treatment as the other two species. Thus there is no degree of latency.

	RED CELL PREDILECTION	PARASITIC RANGE (USUALLY)
Plasmodium vivax	Reticulocytes	8 000 to 20 000 per c mm
Plasmodium malariae	Mature red blood cells	Up to 10 000 per c mm
Plasmodium falciparum	All age cells	Up to 500 000 per c mm

Thus it can be seen that somewhat of a limitation is imposed on the first two whereas with the last practically no limit exists in untreated cases implying a much graver prognosis.

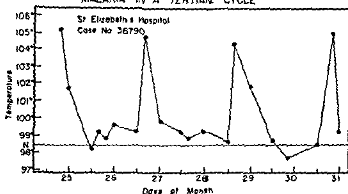
The common pathologic course of benign tertian and quartan malaria is not one of severity but rather one of extensive mildness in which there apparently occurs a balance between the disease and resistive body forces. Undoubtedly there is interplay between body immunity to a species after a time and the invasive powers of the infective species. One apparently becomes weak and the other stronger for the moment only to reverse later.

Prolonged infection sees the exacerbations becoming farther and farther apart with these two species. That the threshold level of clinical manifestation of the disease is raised is evidenced by the fact that so many asymptomatic parasitemias are found in endemic areas. The adaptation of the body to the malarial toxins via immunity or histologic compensation or subsidence of virulence of the species, or all these factors may explain this. The consistency of the pathologic picture in most cases suggests that the time element of change is prolonged so that the whole scheme develops more slowly with a balance occurring between the toxicity and destructiveness of the parasite and the ability of the host to compensate for the invasion and to live compatibly with it.

CLINICAL SYMPTOMS

Paroxysms—Typical

The clinical observations of malaria in the past have led to the common naming of the various species causing it. These are in rather prominent usage today although it is less confusing to use the generic terms such as *P vivax* etc. The clinical terms are respectively benign *tertian quartan* and *malignant tertian or subtertian* malaria. Tertian is derived from the Latin meaning three being applied to *vivax* malaria the chills and fever occurring on the third day. Quartan comes from the Latin meaning four being applied to *malariae* malaria the paroxysms occurring on the fourth day. In each instance the first day is a day of chill and fever in *vivax* and *ovale* and



The spleen and liver in an acute case of malaria are congested enlarged soft and spongy with a dark color The more chronic the case the darker and firmer the consistency The continuous hyperplastic changes which occur in capsular fibers and internal corpuscular tissue elements bring this about The spleen and liver are often three to four times their normal size, with a blackish cast in patients dead of long standing malaria Capillary thrombosis and hemorrhages even moderately larger infarctions have been found to occur

Microscopically highly pigmented cells cloudy swelling and necrotic foci are observed in the liver The phagocytes monocytes and reticuloendothelial cells are heavily darkened with black pigment Vacuolization toxic changes and fatty infiltration all may occur as complications There may be found what is called ring hemorrhages for example capillaries plugged with parasitized red cells and edema in the brain with subsequent development of malarial granulomas Those induced by vascular thromboses are not confined locally but may be widespread over the body occurring in the heart which shows focal or interstitial myocarditis in the nephritic tubular areas pancreas thyroid lungs and suprarenals all usually appearing in fatal cases Focal necrosis and petechial hemorrhage in the gastrointestinal tract are not rare

Acute stages of malaria produce a drop in blood protein and reversal of A/G ratio Blood viscosity is changed and water balance disturbed The effect of these on kidney secretion may cause retention of by products of body metabolism

The overtaxation of the resistive forces of the body and the wholesale destruction of red blood cells by malaria have brought in association to it a clinical term describing a condition found in malarious areas called "black water fever" the pathology of this state being the same as that produced in malaria except that every finding is acutely intensified and the absence of kidney function typifies the clinical picture There occurs in this condition a vastly overwhelming loss of total red blood cells so much that one to two million may be destroyed in twenty four hours Death may ensue in a very short time The species identified most commonly with blackwater fever is *P falciparum* though recently a new malignant vivax strain occurring in children has been reported from Russia In these cases there was found a heavy hemoglobinuria

A state of cachexia will develop in long standing chronic malaria the result of the anemia and impaired function of vital organs needed to maintain good health Intervening intercurrent infection causes complete debilitation or even death There occurs in malignant malaria (*P falciparum*) a greater tendency for the parasitized red blood cells to clump or agglutinate together than is evidenced by quartan (*P malariae*) or benign tertian (*P vivax*) This was observed many years ago in the brain and other organs after death Cropper (1908) found this agglutination in the peripheral blood stream before death Knisely (1941) thought the red blood cell agglutination was in liver passage phagocytized there

irregularly so with *falciparum* malaria, the next chill is forty eight hours later or on the third day The same applies to *malariae* malaria the time interval "Benign" and l outcome of the ated with it the mortality and pathology of the seemingly mild *falciparum malaria* which became known as "malignant tertian" malaria

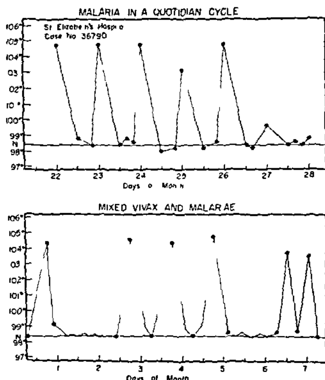

*Fig 3**

The chill fever sweat periodic syndrome is called a paroxysm and varies in length and periodicity with the species The *vivax* and *malariae* paroxysms exhibit variability but occur approximately four to ten hours from the beginning to the end *Falciparum paroxysms are somewhat milder but last upward to* from ten to even thirty six hours In the former two the temperature usually falls to normal or below normal and is considered intermittent whereas in the latter the temperature may not come down to normal but rather remains above it hence it is considered a remittent type and persists longer The typical paroxysm consists of a preceding cold phase (chill) lasting from one half to one hour during which the patient is pale erector pilae spasm is prominent, coarse tremors are evident and a sense of anxiety is obvious The body temperature rises and chilly sensations of wave character pass over the body This is followed by *outright severe tremors and local spasms and chattering of the teeth,*

symptomatology and signs of dilated right sided heart These are found usually at high altitudes connected with a fatty degeneration of the myocardium The *bronchopneumonic* type has symptoms referable to that body area

The subjective experience in clinical *vivax* malaria is usually more harassing than with the others First the prodromal symptoms such as rheumatoid pains etc precede a sudden onset of paroxysm all of which are a severe stress for the patient These may have a *periodicity* *For the most part the* paroxysm even if somewhat irregular at the start and which may be daily in occurrence always becomes fixed on a forty eight hour recurrent basis Between attacks patients *feel well being able to do their work*

P malariae infection has had associated with it a tendency to some nephritic involvement as a complication Untreated *vivax* malaria and *malariae* infection will by nature of the cell selectivity of the parasite become limited over a period of time whereas *falciparum* malaria on the same basis may exhibit no such limitation

	PARASITES PER C MM	(MAX)	PERIOD COVERED
Plasmodium vivax	20 000 to 40 000	50 000	2 to 3 yr
Plasmodium malariae	5 000 to 10 000	20 000	7 to 10 yr
Plasmodium falciparum	Unpredictable	No limit	2 to 6 mo

Although the incubation period of naturally acquired malaria is approximately *fourteen days that of artificially transmitted malaria is shorter eleven* days (James 1931) Latency is a prominent feature of both *vivax* and *malariae* The initiation of the paroxysm is dependent upon the rupture of the mature schizonts Manson Bahr (1945) has suggested that the syndrome is of the nature of allergy The manifestations of a *relatively nonimmune group* exposed to malarial infection have been observed in the recent war years The latency exhibited by *vivax* even though cases were treated adequately plus thorough drug supervision preceding entrance into endemic areas has *caused considerable* discussion At this point exacerbations are not as frequent as previously This leads one to suspect some resistance is developing as time passes which may or may not be the case but is probable The *paroxysms are apparently* as severe as previously only *less frequent* Few, if any cases of the severe *falciparum* malaria developed since adequate suppressive doses produce successful results

The incidence of multiple infections is *not as uncommon as one would* imagine and when occurring may present an unusual picture The presence of two groups of *vivax* or *malariae* in a patient will ofttimes present a more frequent rise of temperature *(quotidian malaria) until the development of the* schizonts becomes more synchronous as they will tend to do in similar species infection This is as yet inadequately explained Infection by heterogeneous species will usually end with one or the other dominating the clinical picture *for example* if *vivax* and *falciparum* are found the latter, having a subtertian *cycle and attacking* any type cell may dominate in untreated cases If *vivax* and *malariae* are found it is reasonable to suppose that the *vivax* will eventually *dominate* being of the shorter cycle though the extreme latency of quartan will become *evident later* *In this* last incidence the patient would have fever

with a harassed, pinched appearance to the face which may appear to have a bluish cast An attempt is made to keep warm by using any or all means at hand The effect of this varies with individuals some requiring bed rest with almost collapse supportive measures and some at the other extreme proceeding with their work though obviously seriously hampered The mind remains clear if not actually more alert than usual The pulse is increased and respiratory rate is increased but is more shallow The desire for frequent micturition is strong and any attempt to eat may be followed by nausea and vomiting This stage is followed by the hot or flushed phase The face is flushed eyes bright, the body has a red appearance There is a sense of relief attendant to the ending of the cold stage only to be followed by the aggravation of pyrexial symptoms of the hot stage for example headache becomes worse and a feeling of abdominal tenseness around the splenic area may be experienced It is not uncommon to find herpetic lesions around the mouth and nose This stage with a temperature of 104 to 106° F may last three to four hours before the final stage of the paroxysm starts that of sweating The skin previously dry and hot becomes moist and cool The temperature falls rather rapidly and perspiration starts about the head spreads over the body and becomes quite profuse lasting two to three hours Accompanying the temperature fall is a feeling of exhaustion and sleep soon intervenes In the course of a few hours the patient awakens feeling fresh but not free of fatigue The patient is usually well until the initiation of the next paroxysm

Paroxysms—Atypical

The foregoing description of a typical paroxysm is almost invariably associated with the *vivax* and *malariae* species the benign tertian and quartan malaria respectively also with *P ovale* except that with this species the clinical manifestations are somewhat milder The atypical paroxysm can occur in individuals in mild forms producing malarial low grade fever headache and rheumatoid pains in the joints long bones and muscles The symptoms are much like those preceding the onset of a head cold These occur in apparently highly resistant patients or partially treated cases For the most part the atypical paroxysms are associated with malignant tertian subtertian or *falciparum* malaria In this type of malaria several clinical forms have become well known

First is the *algid form* thought to be due to localization of large numbers of parasitized red blood cells in the large and small blood vessels of the intestinal tract and abdominal organs The algid type is characterized by prostration bordering on shock with peripheral circulatory collapse and an associated high fever The patients may exhibit uncontrollable vomiting severe dysentery with bloody stools hemorrhage and purpura Consequently severe malaria is clinically designated according to the most prominent symptom or sign The aggregation of large numbers of parasitized red cells in the brain usually results in the *cerebral type* which features delirium coma meningismus aphasic or hemiplegic signs There are other types that have *cardiac*

and besides gastric disturbance anorexia etc there may occur tendencies to hemorrhage There may be a Banti like syndrome in the picture of cachexia The skin will ulcerate easily from abrasions etc *As in many chronic illnesses* the true character is overshadowed by subsequent developing conditions such as deficiency polyneuritis paralyses amblyopia etc The mental depression deterioration of memory and lack of concentration powers that have been associated with malaria infections and malarial debility have been found rarely if at all in Service developed cases of malaria during World War II

General Considerations

Through the many years of observation on malaria several factors have been associated as being incident to the relapses of malaria clinically How these operate is obscure and open to scientific criticism but the dictates of good judgment and common sense place them in close proximity to recurrences of clinical exacerbations of latent and relapsing malaria These factors are overindulgence in alcoholic beverages *undue exposure to elements fatigue* shock surgical procedures childbirth etc Many authorities believe these to be contributing factors in the cause of recurrent malaria

Malariae (quartan) *is considered the worst offender in this regard* especially in view of the many years this species will persist The patient is usually symptomless and the parasites undiscoverable in blood and in the organs though obviously *they* are garnered somewhere in *the body only to* produce relapses when the conditions are right These relapse periods vary in artificially induced malaria and the naturally acquired ofttimes terminating spontaneously in the former (Boyd and Kitchen 1937) Much emphasis has been placed on the relapses occurring in Service acquired *vivax* malaria Since the relapses happen frequently they may constitute an economic burden *on* the patient in his usual pursuits However quartan malaria relapses run into many years benign *vivax* is not expected to do this

The question naturally arises *what influence does the malarial disease* have on other conditions? The transmission of malaria *congenitally is yet an* open question There are incidences where the malarial parasites have been found in the newborn but in some *there* has been *some abnormality connected* either with intrauterine life or with parturition When fetal infection does occur it *must* place a severe burden on the child There are other cases where it appears that congenital infection has no doubt occurred *most likely via* the placental route (James Brown Tanner Hewitt) Clark (1928) on the other hand has made extensive surveys with this point in mind and found no crossover to fetal blood of parasites even though the mother was heavily infected Treatment of this is discussed under Therapeusis There are many *cases reported and on record* of malarial infections developing from the transfusion of blood from a donor who has an asymptomatic malaria *or who has* had history of previous infection The interval of time between *clinical malaria in the donor* and the transfusion time to the new case has been as long as several decades The species involved has usually been *P malariae*

twelve days in nineteen Perhaps there would be a double rise in temperature on the seventh thirteenth and nineteenth days as *vivax* and *ovale* produce chills every forty eight hours and *malariae* every seventy two hours *Falciparum* produces them irregularly from approximately thirty six hours onward The symptoms are mild almost insidious until the more severe clinical malaria occurs Table VIII represents clinical symptomatic differences

TABLE VIII

	TERTIAN	QUARTAN AND SUBTERTIAN
Seriousness	Nonkilling	Killing
Distribution	Global but spotty	Tropical
Symptomatology	Severe	Milder (insidious)
Course	Regular	Irregular
Relapses	Prone	Less so
Latency	Four plus	Minus
Treatment	Resistant	Susceptible
Prognosis	Good	Guarded

Malarial Debility

The repetition of attacks of any of the malarial species if untreated or inadequately treated may lead to serious debility in physical and mental capacities Here greatly enlarged livers and especially spleens are observed

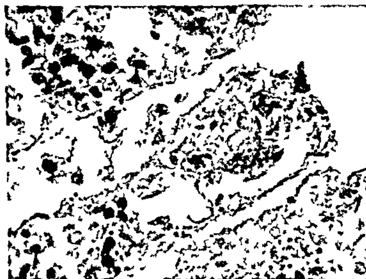

Fig 15 —Malarial intestine (Original photomicrograph of O Felsenfeld.)

The skin is a sallow color the turgor is gone the face is pinched and the ocular sclera is a yellowish color A pot bellied ' type abdomen is found especially in children Growth impairment may be obvious The over all resistance to minor ailments is drastically lowered by the chronic anemia Patients with the more severe type may show ascites and edema of the legs

bite fever or Haverhill fever should be thought of diagnostically In the latter areas add kala azar trypanosomiasis Weil's disease and especially amebic liver abscesses

Endocarditis usually follows some acute infectious process as a complication blood cultures and evidences of bacteriemia irregular periodicity to the daily temperature rise heart murmur help in differentiating it

An exhaustive careful study will perhaps be the best method of ruling out tuberculosis The absence of typical paroxysms and crises, a positive lung x ray *cough hemoptysis and an unexplained moderate polycythemia* are suggestive of tuberculous splenitis Pyelitis usually has symptomatology referable to the urogenital system In early cases only bacteria and some pus may be found as an abnormality in the urine Typhoid fever is apparently easy or difficult to differentiate outstanding features are slow pulse increasing fever each day history of exposure *blood culture early in the disease Urine culture later* or the Widal test is of help Relapsing fever can usually be ruled out using blood smears and finding the causative spirochete during the fever An atypical typhoid type of tularemia can be confusing The lack of positive blood smears for malaria and the use of blood agglutinins for specific tests in the second week will rule out tularemia Foshay's intradermal antigen is considered specific in tularemia Influenza can be ruled out by blood smear examination and absence of catarrhal symptoms Brucellosis can be established by blood culture and by suggestive skin tests read in forty eight hours the presence of agglutinins and the opsonocytophagic index Ratbite fever usually can be determined by dark field or blood smear examination or lymph node puncture, there are usually lymphangitic signs and regional adenopathy in the proximity of the original ratbite Animal inoculation into mice or guinea pigs can be used to differentiate from malaria

Kala azar is in its onset in some cases similar to malaria though a double daily rise in temperature has been found in some areas The finding of *Leishman Donovan bodies by liver or splenic puncture* or using blood to culture the causative Leishmania can usually aid in differentiating this disease from malaria Trypanosomiasis both the African and South American types can be identified by finding the parasites in the blood during the acute phase Winterbottom's sign glandular enlargement in the neck together with finding the parasite are reliable in establishing a diagnosis of African trypanosomiasis Gland puncture is not considered very reliable in Chagas' disease (South American trypanosomiasis)

Weil's disease *caused by Leptospira icterohaemorrhagiae, has an abrupt onset in many cases* similar to the start of a malarial paroxysm It can be differentiated by using the blood smear to demonstrate the etiologic agent *during the first few days of the disease thereafter the organisms appear in* the urine Most effective is injecting blood into a guinea pig or hamster, *finding* the Leptospira and positive agglutination tests

Liver abscesses with periodic fever are in certain incidences difficult to differentiate from malaria The blood smears high polymorphonuclear leucocyte count or *antimalarial drug therapeutic* test may be the only reliable

This type of transmission and inoculation has been found also among drug addicts (Applebaum and Gelfand, 1934 Helpern 1934 Jolliffe 1940 and Most 1940)

There are several ways of determining the degree of malarial infection in a locality These means are by using the splenic index parasitic index sporozoite rate in salivary gland (mosquito) or by dissection of the mosquito stomach and observing oocysts All of these are not without fallibility and have their points of controversy The *splenic index* is the number of palpable spleens per 100 persons examined The *parasitic index* is the number of positive blood smears per 100 people The *sporozoite rate* is the number of positive mosquito salivary glands per 100 mosquitoes *Mosquito oocyst index* is the number of positive mosquitoes found per 100 mosquitoes examined The *endemic index* is the parasitic index plus the splenic index Somewhat of a criterion has been advocated on the degree of endemicity as follows

10% or below	Low endemicity
10 to 25%	Moderate endemicity
25 to 50%	High endemicity
50 to 90%	Hyperendemicity

Under natural conditions when the index is below 10 per cent the other 90 per cent must have either quiescent malaria or no malaria The thought has been suggested that this may be the type of situation where an increase in malaria could be expected on the basis of so many being more or less susceptible (Komp and Clark 1934)

DIAGNOSIS

The diagnosis of malaria rests on (1) positive blood smear (2) periodic fever and paroxysms or periodic symptoms (3) splenomegaly (4) history of malaria or of having been in an endemic area (5) the judicious ruling out of similar conditions producing a complicated malaria picture (6) the complement fixation test which has been found to be suggestive and apparently worth while in patients of a quiescent malarial phase (Coggeshall and Eaton 1938) (7) drug therapeutic tests with antimalarials (8) pigmented leucocytes in the presence of leucopenia with a relative increase of monocytes which is suggestive

DIFFERENTIAL DIAGNOSIS

Malaria can unfortunately simulate almost any disease consequently many other conditions must of necessity enter into the process of differentiation and the ascribing of a malarial state The geographic location of the case will afford some help in this If in a nontropical area the tropical diseases can be eliminated fairly easily from consideration they should be borne in mind if the patient has recently returned from the tropics If the patient is in a tropical area both temperate and tropical diseases must be considered. In the former area diseases such as septic states endocarditis tuberculosis pyelitis typhoid fever, relapsing fever tularemia influenza brucellosis rat

measures in these cases.* Those abscesses due to *Endamoeba histolytica* can be identified by using what appears to be a significantly reliable test, the amebic complement fixation procedure.

Filariasis can be differentiated by unilateral swelling and adenopathy and by blood smear and serologic methods. Yellow fever has a more prolonged onset. Albuminuria occurs on the second or third day with mild jaundice, but blood smears will aid in establishing a diagnosis of malaria.

Chronic malaria and hookworm disease can be differentiated by laboratory methods: blood smears or finding the nematode eggs in the stools.

Blackwater Fever

For the purposes of complete understanding a few clinical points regarding this condition are included under this section. Blackwater fever associated with *falciparum* malaria is fortunately not too common. One Navy clinician who spent more than a decade in malarial areas saw only three cases in nine years in nonimmune individuals who had entered a *P. falciparum* endemic area and resided there for only a short while. The disease appeared with the swiftness of an allergic phenomenon and probably was not too far removed from a state of that character. The patient's malaria seemingly improves, and people native to the area apparently are not subject to the disease. However, natives going from one area to another, for example, elevated regions where one species, *quartan* or *vivax*, is dominant, to sea level areas where *falciparum* is present in great numbers, have fallen victim to blackwater fever. Age or sex seems to make no difference, and the occurrence of the disease tends to be familial in character. A recent suggestion has been offered by Butts (1945) regarding this familial tendency, namely, that the Rh factor may be instrumental in the hemolysis of blood cells in blackwater fever. Factors involved in its precipitation are varied and debatable. These few listed are some, but by no means all, of the factors discussed or considered:

1. Amount of exposure to malaria
2. Fatigue
3. Exposure to debilitating conditions
4. Alcoholic beverage excess
5. Quinine
6. Atabrine
7. Arsenicals
8. Plasmochin
9. Pregnancy
10. Biologic variation in individuals

The pathologic sequence of events can be succinctly summarized as:

1. Hemolysis of parasitized and normal red blood cells at the rate of over 1,000,000 in twenty-four hours
2. Development of hemoglobinuria
3. Early appearance of jaundice
4. Usually azuria. Maegraith (1945) advances the theory that this may be due to renal anoxia.

*Editor's note (O. F.): Paludrine and Chloroquine (Aralen), however, are active also against liver amebiasis.

6 Lobe of pronotum distinctly larger than the *mesonotum* 7
Lobe of the pronotum generally smaller than the mesonotum spiracular bristles present in *Psorophora* and *Theobaldia* fringe of squamula almost always complete Tribe *Culicini* (in part)
7 Spiracular bristles absent (*Haemagogus* *Aretmapodites*) Tribe *Culicini* (in part)
Spiracular bristles present (substituted by scales in *Limatus*) fringe of squamula generally absent or incomplete when present Tribe *Sabethini*
8. Scutellum slightly trilobate Genus *Chagasia*
Scutellum uniformly rounded 9
9 Stalk of the fourth vein undulant Genus *Bironella**
Stalk of the fourth vein straight Genus *Anopheles*

KEY TO ADULTS OF THE SUBGENERA OF AMERICAN ANOPHELES

1 Mesonotum with narrow median white fringe body without scales in the female the hairs of the antenna are as long as the width of the thorax all wing scales are black small mosquitoes *Stethomyia*
Mesonotum with two median longitudinal black bands and two dorsal stripes in the female the hairs of the antenna are not as long as the width of the thorax costa of the wing with four or five white spots alternating regularly with black spots abdomen without scales *Kerteszia*
Mesonotum and costa marked otherwise 2
2 Scales of the costa subcosta and first longitudinal are more abundant than in the rest of the wing forming a distinct contrast petiole of second marginal cell is one third to one half the length of this cell wings with scales of uniform coloring or only with light colored scales in the fringe of the apex *Coelodiazesis*
Abundant scales on all veins or with only the costa bearing the more abundant scales 3
3 The third fourth and fifth segments of the posterior tarsus entirely white or with narrow black rings these segments show different spots in the median anterior tarsus 4
The third fourth and fifth segments of the posterior tarsus entirely black or with narrow light spots 6
4 Abdomen with scales or bands of scales posterolaterally at least in the last segments 5
Abdomen pilose only the genital segment bearing scales sixth longitudinal wing vein with large black spots *Myzorhynchella*
5 Sixth longitudinal wing vein with small black spots near the extremities, wing scales not broadened *Nyssorhynchus*
Sixth longitudinal wing vein with numerous tiny spots with one outstanding central spot wing scales very broad *Shannoniella*†
6 Apical third of *posterior femur* covered with erect black scales, wings with white yellow and black scales *Lophopodomyia*
Apical third of posterior femur without erect black scales 7
7 Spotted aspect of wing due to grouping of some dark scales, *light scales only in the* apex of the costa first longitudinal and in the region corresponding to the fringe petiole of second marginal cell is 40 to 50 per cent of length of cell *Pussellia*
Wing with scales of uniform color which give a spotted appearance due to their grouping *without light-colored scales* in first longitudinal and with a petiole of second marginal cell which is more than 60 per cent of length *of cell* or wing with numerous light colored scales in various veins 8
8 Single proepisternal seta sixth vein *entirely* black or with only a small median spot *Arthuromyia*
Generally with more than *four proepisternal setae* sixth vein entirely black or having up to five black *spots* *Anopheles*

*Present only in New Guinea and adjacent islands
†The validity of this subgenus is doubtful

CHAPTER 7

MALARIA CARRYING MOSQUITOES AND THEIR CONTROL

Luis Vargas

INTRODUCTION

The classification of the anophelines most widely accepted by modern authors is that of Edwards (1932) which recognizes three genera Chagasia Bironella and Anopheles the last with three subgenera for the American species Stethomyia Anopheles and Nyssorhynchus Following the work of Edwards new additions have been made to the subgenera Vargas (1943) described Russellia

At the present time the subgenus Anopheles is represented in the New World by thirty one species divided into two groups Anopheles and Arribalzagia

In the following key to systematic classification the section referring to subfamilies and genera is taken from Edwards (1932) and the section referring to tribes is from Lane and Cerqueira (1942) with slight modification

KEY TO SUBFAMILIES AND TRIBES

1 Subcosta long extending to and reaching the costa, vein 1 with four branches, vein 2 bifurcated vein 3 simple cross vein 1—2 absent vein 4 bifurcated cross veins 3—4 and 4—5 present vein 5 bifurcated vein 6 long and following margin of the wing auxiliary vein absent or very diffuse (Family Culicidae 2
Without the above listed combination of characteristics other Diptera

2 Antenna with 14 segments subcosta terminating at or before base of vein 2 mouth parts short scales absent Subfamily *Dixinae*
Antenna with 13 segments subcosta terminating much beyond the base of vein 2 scales present 3

3 Mouth parts short palpi curved scales for the most part confined to margins of the wings Subfamily *Chaoborinae*
Mouth parts modified to form a long proboscis palpi not curved wing veins and legs bearing scales (Subfamily *Culicinae*) 4

4 First abdominal tergite without scales posterior coxa slightly shorter than the mesepimeron posterior margin of scutellum always rounded (slightly trilobate in *Chagasia*) palpus of female approximately the size of the proboscis (shorter in *Bironella*) squamula with complete fringe Tribe *Anophelini* 8
First abdominal tergite with at least one spot posterior coxa distinctly longer than the mesepimeron 5

5 Scutellum always rounded at the posterior margin palpus of female longer than the antenna rig 1 external half more slender, flexible curved back squama with fringe absent Tribe *Megarhinini*
Scutellum trilobate palpus of female much shorter than the proboscis flexible with external half not curved 6

SPECIES	BREEDING PLACES	DISTRIBUTION
claviger (*bifurcatus* Meigen, 1818) Meigen, 1804	In cisterns, shallow pools, water collections in rocks, in wells	Southern Europe, North Africa, Asia Minor, and Turkestan
fluviatilis James, 1902 (*listoni* Liston, 1901)	At the headwaters of piedmont streams, pools of water, in streams, springs, and drainage canals, at times in bends of marshes, in lakes and ponds	Turkestan
maculipennis labranchiae Falleroni, 1926 (*labranchiae atroparvus*) (*labranchiae labranchiae*)	In salt water of coastal marshes, in warm fresh water of rice fields, in highland streams, in sun or partial shade	Coasts of Dalmatia, Italy, Southern Spain, Sicily, Sardinia, Corsica, Northwest Africa
maculipennis messeae Falleroni, 1926	In sunny, cold and fresh, stagnant water, large rivers, lakes and marshes	From Norway and Sweden south to Italy, eastern Mediterranean, from British Isles to north shore of Black Sea, Asiatic Russia
maculipennis typicus Meigen, 1818	Fresh water, lowlands and hills	See *messeae*
pharoensis Theobald, 1901	In swamps, floodlands, and rice fields with much vegetation	Palestine, Egypt
sacharovi Favre, 1903 (*elutus* Edwards, 1921)	In sunny inland and coastal marshes, fresh or brackish, slow streams	Italy, Sardinia, the Balkans, Russia, Palestine, Iran, Iraq, North Africa, West China
sergenti (Theobald, 1907)	In rice fields, borrow pits, canals with slow current and dense vegetation, seepage water	Canary Islands, Algeria, Tunis, Egypt, Palestine, Syria
stephensi Liston, 1901	In wells, cisterns, flower pots, tile drains, and covered irrigation canals and other temporary water receptacles, especially in inhabited communities	Arabia, Iraq, Iran
superpictus Grassi, 1899	Standing pools, small streams, rivers and irrigation drains, generally in mountainous regions, prefers edges of water	Southern Europe, Southwest Asia
	Oriental Regions	
aconitus Donitz, 1902	Irrigation ditches, dams, reservoirs, ponds, rice fields, tide water, pools in river beds, ruts in roads	India, Ceylon, Burma, Siam, Indochina, Malaya, Sumatra, Java, Borneo
culicifacies Giles, 1901	Commonly in fresh, clear water, pools, borrow pits, farm wells, rocky or sandy river beds, rice fields, and occasionally in salt water	India, Burma, Ceylon, Siam, French Indochina, and southern Arabia
fluviatilis James, 1902 (*listoni* Liston, 1901)	See Paleoarctic region	India, Burma, Siam, French Indochina, Ceylon
hyrcanus Giles, 1900	Especially in rice fields, in stagnant water with vegetation, in canals, borrow pits, lakes, and stream banks	India, Ceylon, Burma, Siam, Indochina, China, Malaya, Sumatra, Java, the Philippines, Borneo, Iran
hyrcanus var. *sinensis* Wiedemann, 1828	Stagnant water in rice fields, marshes, and ponds and irrigation channels, sometimes along shores of streams and lakes	India, Burma, Indochina, China, Korea, Japan and Formosa, Netherlands East Indies

LIST OF THE ANOPHELES MORE IMPORTANT IN THE TRANSMISSION OF MALARIA

SPECIES	BREEDING PLACES	DISTRIBUTION
	Neoarctic Region*	
albimanus Wiedemann, 1821	In clear, sunny, stagnant, fresh or salt water	Southeast Texas, northeast Mexico
maculipennis var. *freeborni* (Meigen, 1818) Aitken 1939	In fresh, clear seepage water from rice fields, drainage ditches, canals and streams	Pacific slopes of United States, northwestern Mexico
pseudopunctipennis Theobald, 1901	In clear, sunny water rich in algae	Southern United States, Northern Mexico
punctipennis Say, 1823	Shaded stream beds	Southern United States
quadrimaculatus Say, 1824	In fresh water, pools, swamps, slow streams, partially shaded or entirely in the sun, with vegetation	Northeast and southeast Atlantic coast from New Hampshire, Ontario and Minnesota to Mexico
	Neotropical Region	
albimanus Wiedemann, 1821	See Neoarctic region	Mexico, Central America, northern part of South America, West Indies
albitarsis Lynch Arribalzaga, 1878	Among surface aquatic vegetation in large ponds, marshes, lagoons, flood water, inundated bayous, and large bogs with not very shady vegetation	*Central America from Guatemala to Northeastern* Argentina and Paraguay, Trinidad
aquasalis Curry, 1932 (*tarsimaculatus* in part)	In stagnant *brackish pools* from tidal swamps, sunny or shaded, less often in fresh water *rice fields* many *miles inland*	Central America (Nicaragua, Panama), Trinidad *and the lesser Antilles, southward to Brazil*
bellator Dyar and Knab, 1906	Rain water collected at the leaf base of bromeliads, shade trees	From Trinidad and Venezuela to Brazil
darlingi Root, 1926	Among surface aquatic vegetation in fresh, *clear*, shaded water of lagoons, flooded lands, *muddy* pools	Central America (British *Honduras* and *Guatemala*), South *America* (Colombia, Venezuela to Argentina)
gambiae Giles, 1902	Grassy pools, streams	Brazil
noroestensis Galvão and Lane, 1937	In fairly sunny waters as well as in shady places	*Brazil*
pseudopunctipennis Theobald, 1901	See Neoarctic region	From Mexico southward to Chile and Argentina
punctimacula Dyar and Knab, 1906	In shaded pools with stagnant water, morasses, and slow moving currents	From Mexico to Peru and *Brazil*
tarsimaculatus Goeldi, 1905	Pools	*From Colombia to Paraguay*
	Paleoarctic Region	
maculipennis atroparvus van Thiel, 1927	In brackish water of coastal areas, fresh inland water, prefers sun	From Sweden to the maritime provinces of Russia, Germany and Holland *from British Isles to Japan, from Portugal to* Italy, Mongolia

*Other valid species in the U. S. A. are:
A. *occidentalis* Dyar and Knab 1906 (*A. earlei* Vargas 1943)
A. *aztecus* Hoffmann 1935, in waters in Mexico
A. *georgianus* King 1939, deep southeast of U. S. A.
A. *bradleyi* King 1939, *along the east coast of the U. S. A.*
A. *walkeri* Theobald 1901, *a day biter in the East of the U. S. A.*
A. *crucians* Wiedemann 1828, in acid waters, southeast U. S. A.
A. *atropos* Dyar and Knab 1906, in salt waters of the Atlantic

SPECIES	BREEDING PLACES	DISTRIBUTION
	Region of Ethiopia	
funestus Giles, 1900	Grassy clear water, morasses, overgrown banks of brooks, rivers, ditches, banks of lakes, ponds, permanent seepage	Central and eastern Africa northward to Ethiopia
gambiae Giles 1902 (*costalis* Giles 1900)	Small pools of standing water, partly or wholly exposed to the sun, less frequently brackish water	Tropical Africa with the exception of desert and high mountain regions, Madagascar, Mauritius
hancocki Edwards, 1929	Clean shallow water holes with vegetation, ditches and wells, running brooks, swamps	Sierra Leone, Liberia, Cameroons, Uganda, Belgian Congo
hargreavesi Evans, 1927	In clear water, with vegetation in relatively open wooly areas in marshes, banks of streams	Sierra Leone, Liberia, southern Nigeria, Gaboon, and Belgian Congo
moucheti Evans, 1925	In vegetation on borders of marshy pools, streams, slow moving rivers, in the grass or the banks of permanent shallow morasses	Belgian Congo, Uganda, Cameroon
moucheti var *nigeriensis* Evans, 1931	Clear water with vegetation	Southern Nigeria
nili Theobald, 1904	Shaded banks of slow flowing, clear streams	Tropical Africa
pharoensis Theobald, 1901	See Paleoarctic region	Tropical Africa, Madagascar
rufipes Gough, 1910	Most frequently stagnant or semistagnant pools, sunny stream beds	Transvaal, Rhodesia, Kenya, Uganda, Sudan, North Nigeria, Gaboon

Note —Nomenclature according to American Entomological Society

GENERAL FACTS ON MOSQUITO REDUCTION

Stubbs (1945) uses the word "prevention" rather than "control" of mosquito population, as the latter word carries a connotation of willingness to accept the continued existence of the disease as being inevitable

Soper and Wilson (1942) noted that the term "mosquito eradication" has been widely misused in literature dealing with mosquito campaigns The term "mosquito reduction," not "eradication," is meant

Ginsburg (1944) has clearly stated that the primary aim of mosquito extermination work is to eliminate mosquito breeding This is generally accomplished by such mechanical methods as proper drainage, the filling in of low areas grading establishing of rapid water circulation, depending upon which method is most suitable and least costly for the topography and environment of the area to be protected Where mosquito extermination is impossible or impractical temporary control measures are resorted to The purpose of temporary control is to afford to the community immediate protection from mosquitoes It may be achieved by treating mosquito breeding places with chemicals toxic to mosquito larvae and pupae In unprotected or only partially protected areas where mosquito density has not been reduced to the minimum at which the mosquito ceases to be a discomfort to the community, various indoor and outdoor sprays and repellents against adult mosquitoes are employed

SPECIES	BREEDING PLACES	DISTRIBUTION
jeyporiensis jeyporiensis James 1902	Overflow from rice fields, irrigation channels, muddy banks of streams, lakes and ponds	Eastern India, southern China, Indochina
jeyporiensis candidiensis Koidzumi 1924	Irrigation ditches	India, China, Indochina, Burma and Formosa
leucosphyrus Dönitz, 1901	Shady pools of standing water in jungles, rocky beds of mountain springs, hoof prints	India, Ceylon, Burma, Indochina, Malaya, Sumatra, Java, Borneo and the Philippines
maculatus Theobald, 1901	Mostly in sunny stream beds, seepage, rice fields, ditches	India, Ceylon, Burma, southern China, Siam, Malaya, Indochina, Netherlands East Indies, Formosa, Philippines
minimus minimus Theobald, 1901	Slow moving currents of clear sunny water, grassy springs, irrigation ditches and rice fields	India, Ceylon, Burma, Assam, Siam, Indochina, China, Formosa
minimus flavirostris Ludlow, 1913	Frequently in clear water of shady springs around bamboo roots	Philippine Islands
novumbrosus Strickland 1916	Standing pools in woodlands, drainage ditches, swamps	Malaya
pattoni Christophers 1926	Beds of mountain streams, pockets of water in banks of streams with vegetation, *pools of rainwater in rocks*	Northern China, Japan, Korea
philippinensis Ludlow 1902	Tanks, standing pools, drainage channels, ditches, swamps, borrow pits, rice fields	Western India, Burma, Malaya, Siam, Indochina, Netherlands East Indies, Philippines
sergenti Theobald, 1907	See Palearctic region	Northwestern India
stephensi Liston 1901	See Palearctic region	India, Burma
subpictus Grassi 1899 (*rossi* Giles, 1899)	In temporary and permanent *accumulations of water, salty or contaminated by sewage*	Indies, southern China, Malaya, Netherlands East Indies
sundaicus (Rodenwaldt 1925) (*ludlowi* Theobald 1903 var. *sundaica* Rodenwaldt 1925)	Brackish pools, lagoons and *marshes formed by sea water, accumulations of salt water behind dikes and similar structures*	Eastern India, Burma, *Siam, Malaya, Sumatra, Java, Borneo, Little Sunda*
superpictus Grassi 1899	See Palearctic region	*Asia Minor to northeastern* India
umbrosus Theobald 1903	Pools of standing water and shaded woodland mires, peaty marshes in jungle	India, Malaya, French Indochina, Sumatra, Java, Borneo, the Philippines
varuna Iyengar 1924	Stagnant water in tanks, banks of springs, irrigation canals, wells	India and Burma

Australian Region

SPECIES	BREEDING PLACES	DISTRIBUTION
aconitus Dönitz 1902	See Oriental region	Celebes
hyrcanus Giles 1900	See Oriental region	Celebes
punctulatus Dönitz 1901 (probably *farauti* Laveran 1902)	Small sunny pools of rainwater, swamps, sea beds in large bodies of water	New Guinea, Timor, Melanesia, Northern Australia
punctulatus (*moluccensis* Swellengrebel and de Graaf, 1920)	Fresh or salt water, clear or polluted	Moluccas, New Guinea, New Britain, Solomon Islands, New Hebrides, Admiralty Islands, Northern Australia
subpictus Grassi 1899 (*rossi* Giles 1899)	*See Oriental region*	New Guinea
umbrosus Theobald 1903	See Oriental region	Celebes

The first step in any malaria control program should be the assembling of facts and information bearing on the location of areas in which the disease is a problem

The more common types of surveys are blood surveys spleen surveys anopheline surveys engineering surveys and economic surveys The data obtained are plotted on maps to show foci of infection

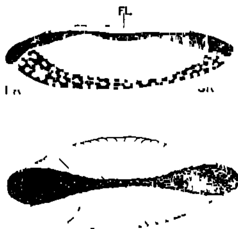

Fig 36 Egg of *Anopheles albimanus* FL floats FP frill GR exochorion.

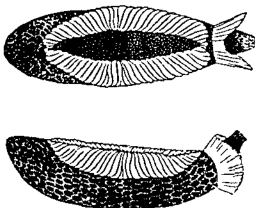

Fig 3 Egg of *Anopheles hectoris*

According to Russell (1947) valuable information concerning incidence and distribution of malaria can be obtained in a short time by examination of local children between the ages of 2 and 14 years for signs of splenic enlargement It is generally possible to attract nearly all the children of a native community to a central place by using such suitable rewards as candy beads pennies etc They will usually permit palpation for splenic enlargement and even the taking of blood smears The use of slides with a thick

light baited are useful Observations should be made of the biting habits of the different species to determine whether they bite by day or by night or whether they bite early in the evening or otherwise It is also important

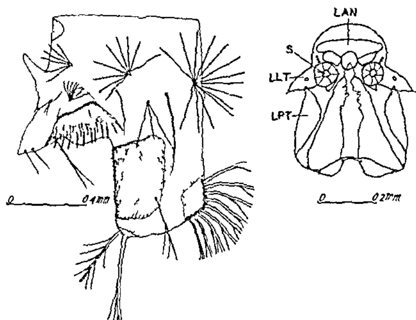

Fig 43 —Terminal segments of the abdomen and spiracular apparatus of *Anopheles fo st* *LAN* anterior plate *LLT* lateral flap *LPT* posterior plate *S* spiracle

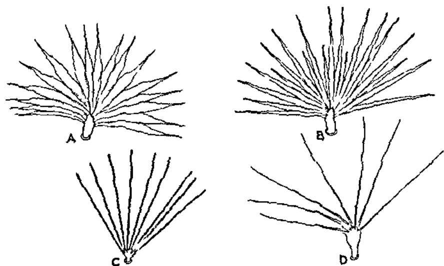

Fig 44 —Palmate hairs of subgenera of *Anopheles* *A* *Anopheles* *B* *Nyssorhynchus* *C* *Russel la* *D* *Kerteszia*

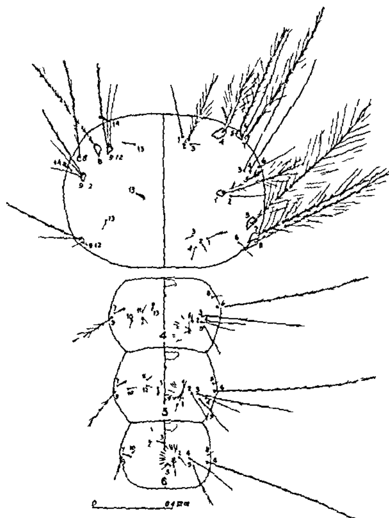
to know whether a species spends its resting hours inside habitations where it is easily attacked or whether it leaves the house at sunrise to rest outside on vegetation or in cuts depressions wells stone walls etc

smear at one end and a thin smear at the other is the best method The thin smears are examined only when confirmation of species is required

In any area under study, every type of mosquito breeding place should be sampled and the mosquito larvae identified No type of water collection from coconut shells and tin cans to wells pools ponds ditches, streams and marshes, should be neglected



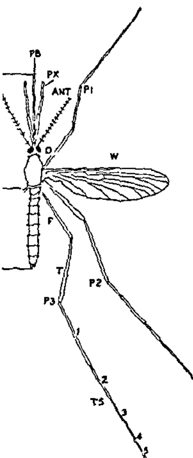


Fig 42 — Illotaxy or chaetotaxy of the thorax and abdominal segments of *Anopheles fausti* right half of diagram showing dorsal hairs left half ventral hairs

Adult mosquitoes should be collected from all types of resting places not only in habitations but also in outdoor shelters such as hollow trees underent banks and the sides of wells The collection should be made both by day and by night Hand-collecting tubes as well as traps both animal and

Mosquito breeding places vary. Those commonly encountered and readily accessible are large areas of swamps and marshes, road ditches, catch basins, ornamental ponds, water accumulations in furrows in vegetable gardens, in hoofprints of horses and cattle in pastures, etc. The kind of oil or larvicide and the type of sprayer as well as the method of application will depend upon the location and the character of the mosquito breeding place.

By spraying DDT *inside* houses, our efforts are directed against adult mosquitoes especially the females Used in this manner, DDT will possibly

eliminate or at least significantly reduce arthropods such as bedbugs, flies, *Aedes aegypti*, and others which serve as carriers of disease—dysentery, dengue, yellow fever, etc. The purpose of spraying DDT inside houses is not to kill the very last Anopheles but rather to control the transmission of malaria.

HOUSING

Kiker (1941) stresses the point that the only completely effective mosquito control measures are those which permanently eliminate the breeding areas, usually by drainage. The principle of this method is also applied to bodies of water which cannot be drained, such as impounded lakes. In these waters environment unfavorable to anophelines is produced temporarily at proper intervals by changing the water level. The method is combined with other measures which tend to prevent growth of marginal vegetation.

Observation of the fact that most anophelines confine their search for blood to evening and night hours when families are usually in the house has led to a search for methods of preventing entry of the mosquitoes. Mosquito proofing has been advocated by many workers. The project involves not only providing screens for doors and windows but also for closing all openings through which mosquitoes may enter a house. Where cracks in walls or floors are extensive, tar paper roofing is laid over the floor and a heavy craft paper is tacked on the walls. Plywood screens are made to fit tightly over fireplace openings (Stromquist 1944).

NETTING

Russell (1943) states that nets to protect sleeping individuals are useful in preventing malaria when they are properly employed and properly maintained. The mesh of the net should not exceed 0.050 inch (0.13 cm) to exclude all species of mosquitoes.

SCREENING

As Riley states, screening of habitations has proved to be both cheaper and more effective than mosquito bars. Today (1948) mosquito bars cost from two and one half to three dollars each. The average family requires two bars. These bed nets last only a year and serve to protect only those in bed; during the hottest weather the nets are apt to be unused because they keep out the few prevailing slight breezes.

Screens, on the other hand, protect the entire house. They cost from eight to ten dollars and last from three to five years and even longer, depending largely upon the care. They can be renewed at much less than the original outlay by rescreening the frames.

Suitable Wire and Proper Mesh

In the tropics, especially at the seaside, it is better to use wire of non-corrosive material such as bronze or aluminum. A hard drawn wire 99.8 per cent copper and of heavy gauge (0.015 inch or 0.038 cm diameter), is suitable. Aluminum screens are also good. Plastic netting promises to be a cheap and satisfactory substitute for wire. In general it is not safe to use screening with a mesh larger than 0.0475 inch (0.121 cm). Heavy grade copper wire screening has sixteen squares to the inch (about forty to the centimeter).

Installation of Screening

In installing screening care should be taken to keep breakage to a minimum. Screen doors should open outward and if possible should be on the windward side of a building. Screens should be strongly constructed so that they will not sag or warp. They require springs so that they will close automatically.

DRAINAGE

Drainage still is, and in places where practicable probably always will be, the most desirable method of effecting malaria control through local reduction or elimination of the breeding places of the malaria bearing species of mosquitoes. The rapidity with which the removal of surplus water is effected has an important bearing on malaria control. The malariologist is satisfied if removal is effected before a brood of mosquitoes can emerge.

According to Robertson et al. (1942) open earth ditches are in many instances entirely adequate and frequently the only funds that can be provided are for this cheaper initial construction. Where the finances of a community permit, lined ditches should be the choice on the basis of long life efficiency, and generally lower cost for construction and maintenance.

Kerosene and gasoline may be used as larvicides since they have a marked killing effect but they form a transitory film are expensive and may constitute a fire hazard

Waste motor oils are not highly toxic to larvae They are sometimes used effectively when applied in a fairly thick film Better results are obtained when waste motor oil is mixed with kerosene in the proportion of 1 to 3 with addition (if possible) of about 2 per cent of castor oil The amount of kerosene to be added will have to be determined by experiment

The amount of oil needed to produce a uniform killing film under field conditions usually ranges from 25 to 60 gallons per acre depending upon the nature of the breeding area toxic properties of the oil species of mosquitoes method of application and atmospheric factors such as wind temperature etc

Handling of oil is objectionable from the standpoint of fire hazards especially near shipyards lumber yards ammunition factories and storage places open fire barrels etc

Oil soaked dust may be scattered over the surface of a breeding place Russell (1943) makes the point that oil booms may be used to combat larval drift The larvae are killed by oil soaked sawdust or chaff thrown on the surface of the water above the boom Russell (1943) states that when Diesel oil No 2 is used about 9 gallons (34 liters) are required per acre (about 4 000 square meters) of water surface for complete coverage with a uniform stable film With an ordinary knapsack sprayer of the Panama type one laborer can oil about 5 acres (about 20 000 square meters) of breeding area per day if the terrain is not difficult In general practice the amount of oil necessary to produce a uniform film may vary from 10 to 20 gallons (38 to 76 liters) per acre The amount of floatage and vegetation makes a considerable difference

Usually it is necessary to spread oil once a week

Fuel oil will kill the larvae in less than one hour The amount of oil required ranges from 10 to 30 gallons per acre of water surface depending upon the amount of vegetation or debris present

Where oil is dispersed by currents as in streams and ditches it may be better to attempt constant application For this purpose there are at least three types of continuous oilers none of which is entirely satisfactory A continuous oiler requires a good deal of attention generally uses more oil than would be dispensed over the same areas from a knapsack sprayer and should not be used unless other methods are found impractical

PYRETHRUM

According to Sinton and Wats (1935) the use of pyrethrum flowers for insecticidal purposes appears to have originated in Persia It was introduced into Europe early in the nineteenth century At that time and for many years afterward a powder prepared from the flowers has been used for domestic purposes

WATER FLUCTUATION

Experiments with intermittent irrigation or a so called ' turn system'' to control mosquito breeding in rice fields have brought promising results in India Java Portugal and other places The principle of this method as a malaria control measure involves the periodic withholding of water long enough to permit the surface of fields and channels to become sufficiently dry to cause the death of mosquito larvae The subsurface soil around the rice roots remains moist

Anopheline vectors that breed in streams may be controlled by periodic sluicing A small dam is built to impound water which can be released by manual or mechanical removal of a barrier or by use of automatic siphons

OIL

The use of oil for mosquito reduction was recommended as early as 1793 in an article in *The American Advertiser* of Philadelphia on August 29 A similar suggestion attributed to R Southey was made in the book *Omniana Otiosores* published in London in 1812 But it was not until Howard published his work in 1892 that the application of oil to mosquito control became an established practice

Herms and Gray (1940) give it as their opinion that the correct use of oil or larvicide is to supplement other measures that are in use to eliminate mosquito breeding places They also point out four other circumstances that call for use of oil (1) while pending installation of primary measures (2) as an emergency measure following floods or other unusual conditions (3) as the only available method in a few instances where primary measures such as drainage are not applicable (*i e* impounding reservoirs) and (4) in the relatively few cases where the capitalized annual cost of oiling or larviciding is considerably less than the cost of primary control measures

The following properties are desirable in the ideal mosquito oil quick toxic effect upon larvae and pupae good spread on all kinds of waters rapid penetration through debris and thick vegetation a stable long lasting film odor inoffensive to man absence of injurious effects on fish waterfowl and plant life and low cost (Ginsburg 1944)

The ideal specifications for a larvicidal oil are

Specific gravity 20/4	0 83 0 86
Viscosity (Saybolt Universal at 100° F)	31 43
Initial boiling point	297 414° F (165 230° C)
Final boiling point maximum	800° F (426 7° C)
Spreading coefficient minimum	17 0

The most important disadvantages of the oiling process are (1) the difficulty of reaching the water through a matt of vegetation and (2) the diminution of the effect by the action of wind and rain The chief advantages are the destruction of eggs larvae and pupae of all kinds of mosquitoes ease of obtaining and spraying ease with which results can be observed and of course the factor of nontoxicity

is based upon actual performance in tests These sprays should contain 150 *to 180 Gm of pyrethrin or their equivalent in each 100 c c With either of the* two kinds of sprays about one half ounce (15 c c) is required to spray 1 000 cubic feet (about 28 cubic meters) (3) The third type of product used *by the* Army is pyrethrum in containers holding a mixture of 20 1 concentrate sesame oil and liquid Freon—Freon 12 The preparation can be of 18 ounces *(532 c c) of a mixture of liquid Freon Freon 12* or dichlorodifluoromethylene with 0 8 per cent wax free pyrethrin and 6 0 per cent sesame oil The latter enhances the killing power of the pyrethrin The vapor pressure of the solvent produces the necessary spraying pressure which does not decrease as long as liquid is present in the closed container As the Freon 12 containing the in secticide is sprayed it forms a fine mist from which the solvent evaporates almost immediately leaving the pyrethrum and sesame oil suspended in the atmosphere as a cloud of fine droplets called an aerosol Freon 12 is nontoxic to man and is noninflammable Its role in the spray is simply that of expellent *to disperse the pyrethrum sesame oil*

Popularly known as a " health bomb " each dispenser of this kind is said to carry enough insecticide to fumigate 240 pup tents or a giant bomber or a space of 150 000 cubic feet

Pyrethrum insecticide can be effectively sprayed through any ordinary spray gun used for spraying paint if air pressure of 15 pounds (7 kilograms) or more is supplied Pressure may be supplied from a tank pumped up by hand or from gasoline or electrically driven compressors Solidified carbon dioxide Dry Ice when available in suitably constructed pressure tanks is a good expedient

PARIS GREEN

After the work of Roubaud in 1920 on the larvicidal properties of para formaldehyde trioxymethylene Barber and Hayne (1921) discovered the prop erties of Paris green as an effective larvicide This product has several names among them Schweinfurth green Imperial green Emerald green and *Mitis green*

Bishop (1940) reported no deleterious effect of Paris green upon vegeta tion and gave no evidence of destruction of aquatic organisms that are im portant as fish food

Sweet and Rao (1933) reported complaints of skin eruptions suffered by *laborers engaged in mixing and spreading the Paris green* larvicide The erup tions occurred principally in the axillary inguinal and anal regions They were not serious and disappeared after the workmen had been instructed to bathe and to wash their clothes thoroughly immediately after work

Larvae feeding at the surface ingest Paris green particles This is espe cially true of *Anopheles* larvae *however* when Paris green floats long enough in still water it is ingested by Aedes and by some Culex larvae which feed part time at the surface

Paris green after sinking is usually rendered inert *It does not repel* ovipositing mosquitoes

Steudel (1911) called attention to the possible value of the insecticidal sprays in malaria control Giemsa (1911 1912 1913 1914) finally recommended a mixture consisting of tincture of pyrethrum soft soap and glycerine diluted with water he also reported that the use of a soap solution containing formaldehyde was effective and cheap

In the United States kerosene extracts of pyrethrum flowers began to displace the powder for household use (about 1900) As a result a large number of proprietary insecticidal sprays are now on the market The active principle in these is derived for the most part from pyrethrum

The name pyrethrum applies to the dried flower heads of *Pyrethrum cinerariaefolium*

Pyrethrin I and Pyrethrin II were isolated from pyrethrum by Staudinger and Ruzicka (1924) They are viscous liquids soluble in petroleum ether alcohol acetone ethylene dichloride and in most of the other organic solvents

These two substances are toxic to cold blooded animals such as insects fish frogs crabs and turtles *The pyrethrins are harmless to warm blooded animals* when taken by mouth

Ginsburg (1930 1939) has developed the New Jersey pyrethrum larvicide It is essentially an oil emulsion of approximately the following composition 66 per cent kerosene or similar light petroleum distillate 0 07 per cent pyrethrin (equivalent to extract of one pound of flowers analyzing at 0 9 per cent pyrethrin per gallon of gasoline) 33 5 per cent water and 0 5 per cent of a neutral emulsifier such as commercial sodium lauryl sulfate This concentrated stock emulsion is mixed with about ten parts of water before spraying Although the diluted spray contains only about 6 per cent kerosene the small quantity of pyrethrin greatly increases its toxic properties so that when applied as directed it is equally as efficient as the regular mosquito oil in destroying larvae and pupae

Russell (1943) considers the spray killing of adult mosquitoes with pyrethrum extract as one of the most important measures of malaria control When used against malaria vectors which rest indoors during the day this solution will destroy a high percentage of the infective mosquitoes of an area and will destroy also many potential vectors The spray also acts as a repellent keeping mosquitoes away from sprayed dwellings and from circumscribed outdoor areas which have been sprayed

The United States Army used three types of pyrethrum products (1) 1 20 concentrate each gallon (3 8 liters) containing the oleoresins of approximately 20 pounds (9 kilograms) of flowers with no less than 75 to 100 Gm of total pyrethrin per gallon (2 to 2 5 Gm per 100 c c) This concentrate in Army practice is diluted with 14 parts of good quality water white gasoline and may be used in various types of mechanical sprayers such as those described below (2) A prepared ready to use pyrethrum spray is supplied in areas where there may be difficulty in obtaining kerosene for diluting the concentrate This spray conforms to class AA rating as defined by the United States Department of Commerce (1938) standard specifications The rating

DDT or any other insecticide is not a substitute *for good sanitation such* as the permanent removal of insect breeding areas

It has been demonstrated that malaria can be effectively and cheaply reduced *in towns and villages* by spraying the interior of houses

DDT with Thanite (*terpene thiocyanoester*) *gives a strong knockdown* and high kill "

Experiments made in Arkansas during the summer of 1944 show that a *single application of DDT* greatly reduces the number *of mosquitoes* resting in buildings during the day *for a period of about 130 days The experiment* also indicated that enough adults were killed to lower the larval population breeding in rice fields by more than 50 per cent

Since *DDT* attacks both adult and larval stages of the mosquito spraying results in immediate kill *as well as affecting future breeding DDT is water* insoluble and must be sprayed either in powder form or in solution in organic solvents such as kerosene xylene o dichlorobenzene etc or in water emulsion *Two quarts of 5* per cent solution per acre *have* given complete protection for several weeks

Solutions of 2 5 per cent DDT in kerosene gave effective control of anopheline larvae when applied by boat oiling units at a rate of approximately *0 1 pound of DDT per acre making possible* a reduction *of about 98 per cent in* the amount of kerosene normally used

DDT had to be mixed with 95 per cent soapstone before a satisfactory airplane dusting combination was obtained With this mixture 90 per cent *control of A quadrimaculatus larvae was effected over 200 foot swaths at rates* as low as 0 05 pound per acre Certain polymethylnaphthalenes (Velsicol) having a high solubility and a high boiling point were found to be ideal solvents for making liquid solutions of DDT to be applied by airplane One *objection to airplane sprays in this instance is their invisibility* The high visibility o [illegible] ing swath

DDT dusts applied at rates of 0 1 pound per acre gave [illegible] f *injury to aquatic organisms* other than mosquitoes but 5 per cent solutions of DDT in kerosene applied at rates of 0 1 to 0 25 pound per acre were quite destructive to populations of aquatic insects living in close contact with the water surface especially *Hemiptera and Coleoptera* Water boatmen (Corixidae) were especially susceptible to the DDT spray Actual dipping records showed however that 20 per cent solutions of DDT in Velsicol applied as thermal aerosols at rates of about 0 12 pounds *DDT* per acre gave very efficient *anopheline control* without significant reduction of other aquatic organisms such as May fly larvae midge larvae beetle larvae and water fleas (Cladocera)

DDT is highly poisonous *to water fleas and fish and to some of the other cold blooded animals* It has killed birds that had fed upon insects killed by the chemical It is deadly to honey bees DDT may interfere with adequate pollination of important food and seed crops and it does destroy *beneficial insects that keep certain injurious pests under control* It is not harmful to

In Paris green mixtures the vehicle may be powdered charcoal calcium hydroxide powdered soapstone road dust or some other dust The vehicle must be well mixed with the poison When lime is used Paris green may be added in the proportion of 10 per cent by weight This is equivalent to about 5 per cent by volume

A Paris green dust mixture can be applied to ponds lakes and large streams by being blown into the air from the windward side so that it will form a cloud and be carried out over the water The large hand operated or motor operated dust blower ordinarily employed in dusting trees in horticultural work may be used to throw the mixture into the air For large bodies of water a slowly settling dust carried along by a light wind will give best results For small bodies of water where vegetation is heavy, or for ditches and streams that are too narrow to be dusted by the cloud' method handfuls of the dust mixture may be thrown directly on or into the vegetation and on the surface of the water There are automatic distributing devices for small canals and streams The airplane may be used to apply the dust over large areas, e g extensive swamps In general the best results are obtained on a sunny day after the dew has evaporated from the vegetation When special distributors are not available Paris green mixed with wet or dry sand clay or any other kind of earth or small pebbles and thrown by hand is often effective

The amount of larvicide required to treat an area will vary with the amount of vegetation When the surface of the water is clear about one half ounce (14 Gm) of Paris green mixed with 99 parts of dust by volume is sufficient to dust 1 000 square feet (93 square meters) of water surface Where the vegetation consists of grass or reeds greater quantities must be used In such places the percentage of Paris green should be from 2 to 5 per cent by volume as determined by experiment

One man can usually prepare and spread Paris green mixture along 1¼ miles (2 kilometers) of bank in one day the exact distance depending upon local conditions

Under average conditions Paris green should be applied at intervals of from five to seven days in warm weather Dusting should be repeated without delay whenever examination of the water reveals the presence of fourth stage larvae Dusting otherwise needs to be applied only often enough to prevent development of first stage larvae and of new broods

According to Watson and Kiker (1938) the cost of operating a dusting plane varies considerably but may be set at about forty dollars per hour An airplane flying at the rate of eighty two miles per hour can dust 33 acres per minute at the cost of 36 7 cents per acre

DDT

DDT acts as a poison for the stomach of the larvae and as a contact poison for the adults Its most remarkable characteristic is its prolonged toxic action the residual effect

Although mosquito repellents contribute toward relief from annoyance, their application on the skin entails inconvenience. *They repel mosquitoes only by actual contact.* To be effective they must completely cover all exposed parts of the body. They cause smarting of delicate parts of the skin, such as eyelids and face. The irritation may become well nigh unbearable to highly sensitive individuals in a warm humid climate when they perspire freely (Ginsburg, 1944).

RELIEF FROM MOSQUITO BITES

Irritation resulting from mosquito bite may be relieved by moist soap. Howard and Bishop (1932) advise wetting the end of a cloth with lather from ordinary toilet soap and rubbing gently on the puncture.

Hoffman (1941) recommends the local application of chloroform.

CHEMICAL PROPHYLAXIS

Russell (1943) emphasizes the necessity of proper treatment of all malarial cases in the work of control of malaria. Drug prophylaxis or chemoprophylaxis has a long history. It was tried against malaria long before the cause of the disease was known. Quinine and Atabrine in small doses are almost equally useful in suppressing the appearance of clinical symptoms after infection. The usual clinical chills and pyrexia are suppressed and do not reappear *until* prophylactic medication has been stopped. Some authorities believe that it is safe to delay the suppressive treatment for three or four days after such treatment has been indicated. There are data, however, which indicate that at least 0.6 Gm. of Atabrine should be taken within a period of two weeks to produce levels in the blood plasma at which suppressive effects are seen.

WILD LIFE

Actual work and study have led to the conclusion that in spite of controversies which may exist between wildlife conservationists and those interested in malaria control, the program of malaria control does not have any serious effect upon wildlife.

PLANTS

Aquatic plants play a dominant role in malaria control inasmuch as they provide food and shelter for the larvae of the vector (Penfound, 1942). Several studies have been made, especially on herbicides, to determine the relation of each species of plant to anopheline propagation and to devise methods of reducing objectionable species to an innocuous state.

Chara foetida has been reported as having a marked lethal effect on mosquito larvae. Shading has been used with some success in control of Anopheles. The factors involved in shading are, on the one hand, the reduction of illumination and, on the other, the retention of moisture by the roots of the plant. Shade may prevent algae and other vegetation from flourishing.

Some success has been obtained in afforesting with *Eucalyptus robusta* to dry the Uganda swamps where *A. gambiae* and *A. funestus* breed.

most plants but does damage squash and other members of the squash family When applied at the rate of 25 pounds per acre, it was found that it could retard growth of some plants The human skin is not harmed by the dry substance or by the water suspensions, and one scientific worker took as much as 1 5 Gm of DDT in butter without ill effects

Massive doses, such as a teaspoonful taken by mouth, or constant and excessive exposure of the skin to DDT oil solution may cause toxic reactions DDT should always be properly labeled It should not be stored near food nor sprayed on food or food utensils

Persons engaged in spraying with DDT should wear coveralls, a wide brimmed hat, goggles, a chemical cartridge respirator, and rubber gloves Persons applying such sprays infrequently need to wear merely coveralls that may be changed after spraying and should avoid wetting the face or any part of the body by the spray When the spraying is done inside the home, all open fires should be extinguished Babies' beds, children's toys, food, or utensils for eating or drinking should not be sprayed Since DDT spray stains glass, pictures and mirrors should be removed from the walls Any liquid spilled should be wiped up Pets should be excluded from the house until the spray dries When DDT dust is applied in a confined area, a dust respirator should be used (Van Keek, 1945)

If skin or eye inflammation occurs from DDT spray, the affected parts may be treated with warm boric acid solution every few hours, if necessary, until a physician is consulted If DDT is swallowed mustard water (one tablespoon of mustard to a glass of warm water) should be taken immediately to induce vomiting Medical help should be enlisted Twenty c c of 10 per cent calcium gluconate has been found useful in DDT poisoning (Vaz et al 1945)

PHENOTHIAZINE

When Paris green and other larvicides are not available phenothiazine mixed with dust or used in water is an effective substitute It is less stable than Paris green but floats better

COPPER SULFATE

Copper sulfate has been used, at final dilutions of 0 1 to 0 25 ppm of water, to kill algae Some species are resistant to this concentration Its use is not generally accepted because of the odor of the dead algae and because of the objectionable taste imparted to the drinking water

REPELLENTS

Various chemicals possessing repelling properties have been recommended and commercialized These chemicals are applied to the skin in the form of lotions, ointments, or powders They may protect the individual for a period of up to several hours, depending upon the repellent properties and other factors, such as thoroughness of application, species and density of mosquitoes, atmospheric factors, etc (see Chapter 65)

Although mosquito repellents contribute toward relief from annoyance their application on the skin entails inconvenience They repel mosquitoes only by actual contact To be effective they must completely cover all exposed parts of the body They cause smarting of delicate parts of the skin such as eyelids and face The irritation may become well nigh unbearable to highly sensitive individuals in a warm humid climate when they perspire freely (Ginsburg 1944)

Some success has been obtained in afforesting with *Eucalyptus robusta* to dry the Uganda swamps where *A gambiae* and *A funestus* breed

FISH

In wells, gardens, and pools without much vegetation, some help in larva control may be gained by use of larva eating fishes, such as *Gambusia affinis*

*Without date.

Although mosquito repellents contribute toward relief from annoyance their application on the skin entails inconvenience They repel mosquitoes only by actual contact To be effective they must completely cover all exposed parts of the body They cause smarting of delicate parts of the skin such as eyelids and face The irritation may become well nigh unbearable to highly sensitive individuals in a warm humid climate when they perspire freely (Ginsburg 1944)

RELIEF FROM MOSQUITO BITES

Irritation resulting from mosquito bite may be relieved by moist soap Howard and Bishop (1932) advise wetting the end of a cloth with lather from ordinary toilet soap and rubbing gently on the puncture

Hoffman (1941) recommends the local application of chloroform

CHEMICAL PROPHYLAXIS

Russell (1943) *emphasizes the necessity of proper treatment of all malarial* cases in the work of control of malaria Drug prophylaxis or chemoprophylaxis has a long history It was tried against malaria long before the cause of the disease was known Quinine and Atabrine in small doses are almost equally useful in suppressing the appearance of clinical symptoms after infection The usual clinical chills and pyrexia are suppressed and do not reappear until prophylactic medication has been stopped Some authorities believe that it is safe to delay the suppressive treatment for three or four days after such treatment has been indicated There are data however which indicate that at least 0 6 Gm of Atabrine should be taken within a period of two weeks to produce levels in the blood plasma at which suppressive effects are seen

WILD LIFE

Actual work and study have led to the conclusion that in spite of controversies which may exist between wildlife conservationists and those interested in malaria control the program of malaria control does not have any serious effect upon wildlife

PLANTS

Aquatic plants play a dominant role in malaria control inasmuch as they provide food and shelter for the larvae of the vector (Penfound 1942) Several studies have been made especially on herbicides to determine the relation of each species of plant to anopheline propagation and to devise methods of reducing objectionable species to an innocuous state

Chara foetida has been reported as having a marked lethal effect on mosquito larvae Shading has been used with some success in control of Anopheles The factors involved in shading are on the one hand the reduction of illumination and on the other the retention of moisture by the roots of the plant Shade may prevent algae and other vegetation from flourishing

Some success has been obtained in afforesting with *Eucalyptus robusta* to dry the Uganda swamps where *A gambiae* and *A funestus* breed

FISH

In wells, gardens, and pools without much vegetation, some help in larva control may be gained by use of larva eating fishes, such as *Gambusia affinis*

unite with the anterior third A flagellum which stems from the blepharoplast is directed forward, following the outline of the parasite, with a few undulations, and extending beyond the anterior end as a free flagellum It is about one half or three fourths the length of the trypanosome The narrow space between the flagellum and the side of the body is occupied by the undulating membrane, which has a few folds

Fig 49 shows a specimen, enlarged 2,000 times, of *T cruzi* in human blood, stained with Giemsa stain It shows the details which permit identification of the species in blood slides

In contrast to other known pathogenic trypanosomes, *T cruzi* does not multiply in the blood This process takes place within the tissues of practically all organs, especially in the cells of the reticuloendothelial system Here, after the trypanosome becomes immobilized, it loses its flagellum and undulating membrane and is reduced to a protoplasmic mass, 3 to 5 microns in diameter, with two nuclei One nucleus, bar shaped, is the kinetonucleus or blepharoplast, the other, more or less circular, properly called "nucleus," through successive binary fission gives rise to clusters, misnamed cysts or residual forms, of leishmanias of *T cruzi*

In Fig 50, in a large endothelial cell of a lymphatic gland, a group of leishmanial elements is seen, with a frequent tendency to produce elongated, flagellated forms Fig 51 shows the same forms in the heart, where they are found more often

Fig 49 —*Trypanosoma cruzi* in human blood Giemsa stain (X2000)

By reacquisition of the flagellum, derived from the blepharoplast, and by progressive enlargement of the leishmania form of the parasite, there occurs transformation into flagellar elements, called *crithidia*, in which state they are capable of multiplication Then, by displacement of the kinetonucleus of the crithidia from the anteronuclear position, which characterizes them, to the posterior extremity, becoming terminal, the crithidia are converted into *trypanosomes* which invade the circulation and begin again the parasitic blood to tissue to blood cycle, with a dual personality, so to speak One form is the trypanosome form, motile and nonreproducible in the blood of mammals but circulating in it *(hemoparasitic)*, the other form is the leishmania form, nonmotile, and not multiplying, evolutive, and adaptable to the tissues *(histoparasitic)* (see Fig 52)

Trypanosomes are ingested by triatomas along with the blood of mammals They undergo special transformation in the digestive tract, particularly in the mid gut of the bug The blepharoplast approaches the nucleus, the undulating membrane is lost, the parasite becomes rounded From these elements originate the crithidial forms, with anteronuclear kinetonucleus Their motility, until the kinetonucleus shifts into the postnuclear but not yet terminal position results in the formation of trypanosomes called "metacyclic" (Brumpt) These are infectious and accumulate in the lower intestine or rectum of the bug and are eliminated with the excreta

Mucosae in general, also the conjunctiva, constitute portals of entry for "metacyclic" trypanosomes from the dejecta of the triatoma Penetration may occur even through the

CHAPTER 8

CHAGAS' DISEASE

SALVADOR MAZZA†

DEFINITION

Chagas' disease is an infectious, noncontagious disease caused by Trypanosoma cruzi (Chagas, 1909) Erroneously believing that during a certain stage in its life cycle in man *Trypanosoma cruzi* multiplied by schizogony, Chagas renamed it *Schizotrypanum cruzi* However being based on mistaken conception, this name was withdrawn by E Chagas in 1934 and the original name given it by C Chagas, *Trypanosoma cruzi*, is now the accepted name of this species

The disease affects several species of animals and attacks at all ages (neither excluding nor preferring children) insofar as man or animals are exposed to contamination by the transmitting bug, a triatoma

This bug inhabits huts and other primitive dwellings or old adobe houses in ancient towns It is a strict hematophagous Hemiptera It is known as "vinchuca" in Spanish American countries, as 'barbeiro" in Brazil and as the "kissing bug" in the United States, because it so often stings the face this frequently being the only exposed part of the sleeping individual (See Chapter 55)

Chagas' disease is also called "American trypanosomiasis" or "schizotrypanosis" It derives its name from Carlos Chagas, who first discovered the vector agent Later, in 1907 he discovered the causative agent, *T cruzi* He described the disease itself in 1909 the natural domestic carriers of the trypanosome (cats, 1909) wild animal sources (armadillos 1912), and, finally the clinical manifestations in detail (1916)

The term "parasitic thyroiditis" heretofore used to designate Chagas' disease, should disappear since there is no justification for its use

THE CAUSATIVE AGENT TRYPANOSOMA CRUZI

(Chagas, 1909)

This trypanosome, in the blood of man, is characterized by the terminal or juxtaterminal position of the blepharoplast or kinetonucleus in the posterior extremity of the body The kinetonucleus, because of its size, extends beyond the sides of the parasite at the posterior end, giving the appearance of an apple with a dagger thrust through it The nucleus, usually ellipsoid or ovoid and compact, is located at a point where the last two thirds of the organism

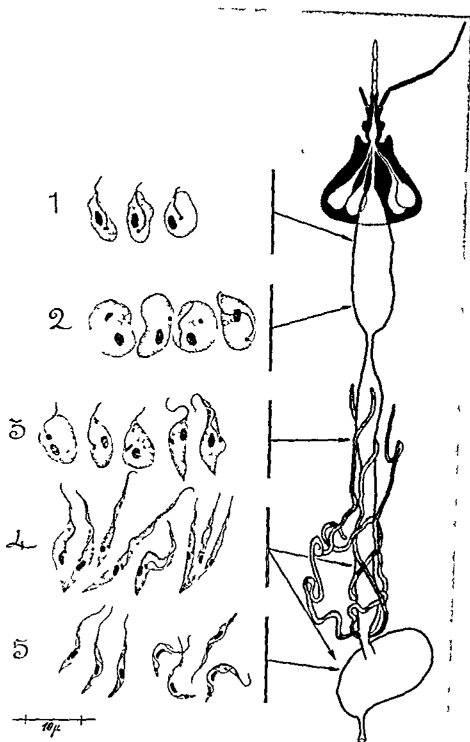

Fig 54.—(Legend on opposite page.)

intact skin, especially in the newborn and in infants In contrast to infection with *Trypanosoma gambiense*, the cause of African sleeping sickness, which enters the human organism by *inoculation* of the trypanosome from the salivary glands of the tsetse fly, the vector, Chagas' disease is a result of *contamination* by excreta of the intermediary vector upon the mucous membranes, on the mucosa of the digestive system, or into the skin, through lesions produced by scratching

The bite of the bug may also cause infection in the presence of moisture which aids the penetration of the trypanosomes from the dejecta deposited frequently by the triatoma while engorging blood or through regurgitation of the trypanosomes from the mid gut to the pharynx and proboscis

Moreover, infection may occur without intervention by the vector It may take place through the placenta, or it may occur through the milk of the mother or the wet nurse if they harbor parasites in their blood, by transfusion of blood containing trypanosomes, by abrasions of the skin of the hands when skinning wild animals which are natural carriers of *T cruzi* (cooks, taxidermists, armadillo hunters, etc), through accidentally spurting blood into the eyes, through contact with the conjunctiva by infected fingers in laboratory personnel

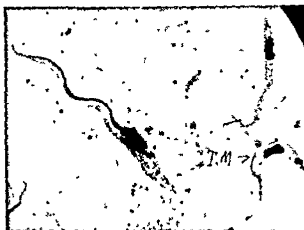

Fig 53 —Dejecta of triatoma with crithidias and a metacyclic trypanosome (*TM*) *Trypanosoma cruzi*

By using the excreta of infested transmitting bugs or the blood of mammals infected with *T cruzi* the parasites may be grown in artificial culture media containing rabbit blood, especially that of Novy Neal and Nicolle (NNN agar) Kelser, or German In these nutrient media after five days, flagellates of crithidia and also the *leptomonas* type may be seen in the water of condensation The latter is differentiated from the former by lack of the undulating membrane

When the culture is inoculated into mammals, trypanosomes appear in the blood, and production of clusters of leishmanial forms takes place in the tissues, especially in smooth and striated muscle, just as when infected blood or infected triatomas are injected

VECTORS

(See Chapter 55)

Natural Reservoirs of Trypanosoma Cruzi

Aside from dogs and cats, quite frequently the carriers of *T cruzi* in homes infected with the trypanosome, there are numerous species of animals with natural infection

The most common of these which have been proved in Argentina are as follows

Edentatae

Chaetophractus vellerosus vellerosus (quirquincho)

Chaetophractus villosus (peludo)

Zaedyus pichyeaurinus (piche)

Dasypus novemcinctus (tatu or mulita [nine band armadillo] of Paraguay)

Tolypeutes matacos (quirquincho bola or mataco)

Marsupialia

Didelphis paraguayensis (comadreja overa) (brown weasel)

Lutreolina crassicaudata paranalis (comadreja colorada) (red weasel)

Canidae

Pseudalopex culpaeus culpaeus (red fox)

Mustelidae

Grisonella huronax (huron

PATHOGENESIS AND PATHOLOGIC ANATOMY

Chagas disease is a protozoan affection of purely an inflammatory type and is not a disease entity of the reticuloendothelial system The predominance of parasites within the cells of the reticuloendothelial system is due to their physical nature since leishmanial and evolutionary forms of *T cruzi* are large corpuscles which strongly stimulate macrophagy of the reticuloendothelium But this macrophagy always occurs toward the end of the inflammatory stage and not in the primary period

The acute primary phase of Chagas' disease is transitory It can be recognized by biopsy of the primary lesion (chagomas) in the skin or of neighboring adenopathy There are foci of acute inflammation at the point of entry of the parasite the infiltrations resembling furuncles or pyogenic phlegmon in its first stages

At the point of the first ectodermic inflammatory focus (the portal of entry of the parasite) there occurs a lymphatic and hematogenous dissemination of the parasite The presence of *T cruzi* in the blood is only an *epiphenomenon* of Chagas disease since fundamentally this is a visceral disease and the most important changes in the development of the protozoa occur in the tissues

During the development of the primary ectodermic infection *the chagoma of inoculation* a typical acute inflammation there occur two essential phases in this infectious focus

1 Multiplication of the parasite, since the invaded animal body does not overcome the infection

2 Lysis or disintegration of some of the parasites which succumb to the infection reabsorption of substances derived from living parasites and flooding of the body by parasites carried in the blood stream Cytologically the reactions of the body to the parasitic invasion are characterized by histiocytic hyperplasia with or without the presence of parasites in lymph glands liver and spleen

The active multiplication of the parasites in the primary focus of infection is followed by early liberation into the blood stream It may occur at

---

Fig 54 —Evolution of *Trypanosoma cruzi* in the digestive tube of *Triatoma infestans* (After M E P R A) (Original of Dr M F Jörg)

At first, Chagas described a period which he called *acute* He extended this period to include the stage of disappearance from the blood of all directly demonstrable trypanosomes After this phase, according to Chagas, there followed another period, the *chronic period,* which lasts throughout the patient's life

Chagas demonstrated *T cruzi* in the blood by direct examination of fresh blood and believed that the acute stage of the disease existed for about one

(After Mazza and Jörg)
action with polymorpho
leishmanias in reticular

denopathy *5* represents
periodically) *6* and *11*
T cruzi with the final

the site of the chagoma or of the neighboring adenopathy Finally, the primary inflammatory focus loses its reactive intensity and there follows a regressive phase of reabsorption and cicatrization and by hematogenous dissemination the attack of the trypanosomes against the tissues begins

The parasites freed from their primary fixation migrate by means of the blood stream into the tissues Here they attack in the manner of parasites in the primary infection The tissue responds with an inflammatory reaction similar to the former However the exudative phase each time becomes shorter because of the formation by the body of macrophages which serve to anchor and isolate the parasite especially when it is large

It may then be said for Chagas disease in man that finding extensive histiocytic macrophagy of parasites with such overwhelming evidence as gigantic cysts or multinucleated plasmodia is simply the end of the focal inflammation as a result of *endogenous reinfection* by *T cruzi* It is the stage preceding that of the cicatrix

T cruzi has the property of rapidly adopting the fertile leishmania form in fixed tissues This parasitic form is probably more resistant than is the evolutionary flagellate form and may also present less antigenic capacity than the other

It is for this reason that with a combination of (1) histiocytic hyperplasia (2) allergy and (3) less antigenic capacity of the leishmania forms there follows *inflammation of endogenous reinfection* practically without leucocytic exudation

The phenomena do not end with macrophagy for despite the fact that focal inflammatory reaction has ceased parasites may again leave this focus to be disseminated throughout the body (the tissues have isolated these leishmanias by macrophagy but the parasites evolve and finally escape the cyst) and the cycle is renewed beginning with the first hematogenous flooding

Because of this fact in Chagas disease a periodic division of morbid states may be made The dual reactions mechanism of infection and endogenous reinfection differ fundamentally in the precise evolutionary movement of the disease process

The primary infection is a very severe attack multiple and simultaneous in many regions of the body which accounts for the seriousness of the infection In the second stage (chronic according to Chagas) the attack is more scattered and there are successive phases so that foci of infection do not exist simultaneously In addition although the cellular reactions are intense they have a changed quality The first inflammatory reactions are almost suppurative intensely exudative and necrotic (ulceration of the chagomas) The later inflammatory reactions are on the other hand more attenuated with more evident proliferation Special technics show that there is a greater specific parenchymatous injury than is true for the primary infection We see a condition quite similar to that seen in syphilis the later reactions are much less inflammatory than the primary or secondary but the parenchymatous lesions are more serious

The *primary period* is characterized by chagoma of inoculation neighboring adenitis reactive local and general adenopathy primary hematogenous dissemination and primary parasitic entrance into the tissues

When the local reaction of primary infection or primary localization (chagoma of inoculation or ophthalmoglandular complex) subsides there appear allergic signs the differential count and myocardial lesions are modified The latter primarily inflammatory now become complicated with alterations in the contractile fibers Thus the patient enters the *secondary period or secondary stage*, characterized by reinfection or by successive endogenous flooding of the system this period is the so called *chronic*" disease of Carlos Chagas

The *tertiary period* is understood to be that which is characterized by an intense fibrous reaction in the inflammatory foci It is the period of myocardial fibrosis in adults fibrous hepatitis etc

The most serious stage in Chagas' disease is the primary period when the first hematogenous dissemination followed by visceral invasion occurs The tissues are overwhelmed by an enormous number of trypanosomes and for this reason inflammatory reactions easily interfere with vitally important functions namely the heart and neuraxis or they may so alter the organic structure that the way is paved for later infection

Thus for example cardiac dysfunction of the primary period is accompanied by passive circulatory pulmonary stasis and by an increased fibrinogen (since it is increased in the blood during this inflammatory stage) Moreover endothelial lesions occur in the lung due to foci of trypanosomiasis all of which with fibrinogenesis and congestion form a fertile field for the development of secondary infection generally bronchopneumonic This is the secondary cause of death most frequently seen in children

In the *primary period* lesions of the central nervous system may lead to a serious meningitis Since specific inflamed tissues are subject to infection it follows that bacterial meningitis secondary to chagasic neuraxitis from the pathogenic point of view is a definite possibility

In the *secondary period* there are to be distinguished two fundamental forms of myocarditis, the dominant visceral lesion in the anatomicopathologic picture in all fatal cases following primary infection These are

1 The early sclerotic form with a picture of progressive myocardial fibrosis with very characteristic morphology

2 The early infiltrative form insidious in its development with rhythmic discharge of parasites into the circulation an anatomicopathologic complex in which are mixed inflammatory foci and extensions allergy secondary degeneration of contractile fibers and moderate sclerosis generally reticular

THE CONJUNCTIVA IN CHAGAS DISEASE IN FORMS WITH OPHTHALMOGLANDULAR COMPLEX

Acute primary conjunctivitis caused by *T cruzi* is a rare complication In much conjunctival biopsy material removed from patients with the ophthalmoglandular complex only a very small number of positives have been

month. However, he cited a case in which parasites were demonstrable in the blood for five months. The thick drop examination of the blood, method of Ross, as a laboratory procedure for the diagnosis of Chagas' disease, has enabled us to find trypanosomes in the circulation for seven to nine months or even longer. *With this fact, the designation "acute stage" has lost its* original meaning as generally understood in clinical practice.

Mazza and Jorg, in 1935, proposed calling the *primary period* or *primary stage* the period of time during which there are present external symptoms indicating the entry of the parasite (the designated *chagmoma of inoculation* or epiphenomenon "palpebral edema" which follows the already established chagasic infection or indicates, very exceptionally, entrance of the infection into the conjunctiva).

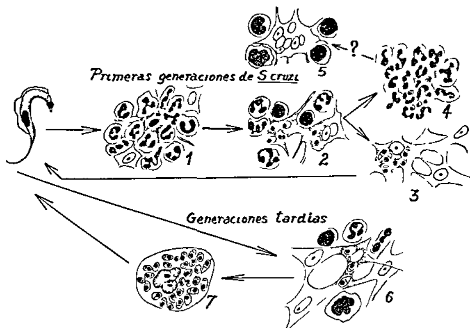

Fig 59.—Differences between inflammatory reaction of primary infection and the successive reactions through endogenous reinfection (After Mazza and Jorg.) (See Fig 58.)

In cases without appreciable external signs, the *primary period* comprises the entire time during which it is possible to demonstrate the parasites by means of simple microscopic examination of the blood. In the absence of trypanosomes, a rather common occurrence in affected adults, the first period is the time during which fever and tachycardia are present.

With the clinical regional polyadenopathy around the focus of *cutaneous primary infection* or *primary localization* (for example facial cellulitis with its characteristic one sided bipalpebral edema of the face) there is always found a gland with inflammatory reaction its size and the surrounding inflammation dominate other *affected glands in that zone*

Histologic study of glands of this character permit their classification as acute adenitis Because of their resemblance to the dominant gland in neighboring adenopathy found in syphilitic chancre ("prefect" gland of Ricard) Mazza and Jorg have designated it 'prefect' gland of *primary chagasic adenopathy*

It can be recognized by the deeply modified and totally obliterated glandular structure Lymphangitis and periadenitis are always found The cortical *zone of the gland is most deeply modified Follicular disposition is always* obscure The subcapsular lymphatic sinuses and primary perifollicular vessels are dilated and filled with the densest histiocytic proliferation The cortical follicles are masked by proliferation and infiltration or are indistinct They are very hyperplastic

The medullary portion is always indistinct and is transformed into monomorphous inflammatory tissue or is sclerosed

The glands can no longer be recognized as such the tissue being changed into dense mottled cellular residue *in which histiocytic proliferation* is always most intense it is compact or inserted sporadically among the remaining lymphatics or nodules or bands may be formed

Apart from this there exist foci of polymorphonuclear infiltration that show a true acute inflammatory aspect phlegmonous or furunculoid always localized in the cortical layer with multifocal necrosis of toxic character Around these foci there is observed hemorrhage with erythrophagy

This acute glandular inflammation is due to the great numbers of leishmanias of *T cruzi* present

Around the prefect gland with acute adenitis of Type I there is frequently found a group of glands enlarged inflammatory but with more at*tenuated manifestations than in the former case* Anatomically and clinically this is primary systematic regional adenopathy or gland lesion **Type II** of Mazza and Jorg (1938)

In these glands *the division between the cortical and medullary layers is* definite although the structure is profoundly altered In the cortical layer the follicles are much enlarged due to histiocytic hyperplasia which forms a clear center Around these there are other newly formed nodules of the same structure which thus fill the cortical layer in which appear bands and irregular masses of densely grouped histiocytes their growth displaces and separates the original lymphatic glandular tissue

The lymphatic sinuses of these glands are filled with dense cellular histiocytic proliferation analogous to the newly formed nodules in the cortical layer In a small number of these glands there are polymorphonuclear foci with small zones of necrosis containing leishmanias

found In these cases there were large numbers of leishmanias beneath the necrotic erosive zone of epithelium Polymorphonuclear infiltration was very dense and formed a layer in close contact with the epithelium but did not deeply invade the choroid

In much of the biopsy material *secondary conjunctivitis* predominated or better, *secondary inflammatory conjunctival reaction* of chagasic origin It is not of primary exogenous origin it is endogenous and is produced by spreading or extension of the neighboring inflammation Cellulitis spread by superficial lymphangitis was found in most of the cases or there was lymphangitis or direct spread of deep inflammation arising from Tenon s capsule or from the cellular orbital tissue

Lesions most commonly found are edema of conjunctiva and choroid and capillary and venous global congestion Extravasation of blood is infrequent

The most important lesion is a subepithelial infiltration with lymphangitis Infiltration consists of plasmocytes exclusively or a few lymphocytes

In a small number of cases the infiltration alone or with a concomitant histiocytic hyperplasia forms nodules which are always subepithelial In somewhat more than half the cases are found foci of intense histiocytic proliferation In a fourth of all conjunctivas histologically examined there were found within the foci of infiltration giant cells (histiocytic plasmodia) Almost invariably their presence coincided with the presence of leishmanias although these generally are not contained within these polykaryocytes

In a certain number of cases the subepithelial lesions are the most recent and present less of an exudative character than those more deeply situated In these cases it is possible to establish that the lesion has advanced from the base to the surface Within the depth there are frequently found gigantic cellular follicles and leishmanias whereas near the surface there is scarcely to be seen a moderate plasmocytic or lymphoplasmocytic infiltration

These cases demonstrate clearly that here is secondary inflammatory conjunctival reaction coming from within toward the surface

GLANDULAR FORMS

Lymphatic Glands — Anatomicopathologic examination of lymphatic glands extirpated from patients at different periods of Chagas disease has enabled Mazza and Jorg to define three fundamental types of glandular lesion designated as Types I II and III

Type I, hereafter referred to as *acute chagasic adenitis* is the most typical and specific of the glandular lesions and is characterized by acute microabscesses necrosis and the presence of many leishmania forms This form of adenitis individualizes the glandular reaction to the manifestations of evident cutaneous portal of entry (chagoma of inoculation) narrows it to cutaneous primary localization in cases in which the portal of infection cannot be seen or where there is no inflammatory manifestation and finally it limits it to primary lymphatic fixation in the septicemic period of Chagas disease without previous adenitic lesions

In fatal cases the dominant lesion is cardiac There is acute myocarditis localized immediately below the epicardium becoming attenuated as it advances toward the endocardium The epicardium intensely infiltrated in some cases shows fibrinous villosities There is always a small quantity of fluid in the pericardium indicative of acute inflammation The endocardium although less affected shows inflammatory foci which reach the muscular spindles At times the conduction system is also affected

Lesions of cardiac fibers as such vary as much in intensity as in other characteristics However in clear cases of pure chagasic deaths there exist regressive alterations in muscular fibers sometimes in the form of very extensive simple inflammatory atrophy sometimes in more varied degeneration waxy grumous or hyaline

In fatal Chagas disease of long duration (ten to twenty years) the dominant lesion has always been cardiac and with the same subepicardial localization as in the acute fatal cases There is observed in these cases fibrinous epicarditis and simple endocarditis with greater intensity and greater sclerosis than are seen in the first period

In such cases the inflammatory lesion of the myocardium develops all the lesions observed in the first period' deaths there are foci at all ages and in the most varied phases of evolution Besides acute infiltration there are found giant cell foci and zones of sclerosis which indicate that chronic myocarditis is present with alternating acute changes or foci of acute inflammation Many of these foci resemble forms found in other chronic infectious diseases

There exist too lesions of the muscle cells sometimes in the form of granulogrumous myomalacia with invasion of macrophages sometimes in the form of degenerative lesions of the striated fibers

The special characteristic of these cases is the periodic renewal of acuteness of the affection we are dealing with an inflammation with perpetual renewal insidiously undermining the myocardium with localized regressive irreparable alterations These patients have an acute myocarditis that increases in severity until death occurs

Hepatic lesions are variable There is frequently steatosis (yellow liver similar to that of yellow fever) and nodular foci of histiocytosis often with leishmanias (Mazza and Jorg) This last type of lesion prompted Mazza to search for it by hepatic viscerotomy in cases of sudden death especially in infants

Acute splenitis with incipient fibrosis is the most characteristic lesion of the spleen as is histiocytic proliferation of the germinal centers of the Malpighian follicles in relation to glandular lesions which we have designated as **Type III**

Changes in the brain are focal corticoencephalitis with proliferation of larger cells and perivascular infiltration and proliferation neighboring inflammatory changes perineuronal acute meningochoroiditis especially in cases of toxic impregnation of the neuraxis and neuraxitis without demonstrable parasites in the nervous tissue

This is the lesion of *attenuated chagasic adenitis* with a high degree of intrafollicular histiocytic hyperplasia It is intrasinusal and corticonodular When this histiocytosis, sinusal or in bands is very greatly disseminated, it may reach the point of reproducing classical *adenitis with clear areas as a residuum of the postinflammatory hyperplastic state of the gland* This is Type III of Mazza and Jorg which these authors later designated as *generalized secondary polyadenopathy* This appears simultaneously with or following regional adenopathy in relation to lesions of mucocutaneous primary infection or primary localization It corresponds to macropolyadenopathy characteristic of the tertiary form of Chagas' disease

These lesions are absolutely nonspecific and are found in glands removed from various regions of the body They are simple reactive cellular hyperplasias with intense histiocytosis in sinusal and follicular epithelioid cells

Lacrimal and Salivary Glands—These are often affected *Chagasic dacryoadenitis* of the lacrimal gland studied at biopsy of the palpebral prolongation of the orbital gland is composed of zones of glandular parenchyma with scant infiltration surrounded by a large inflammatory zone which separates and destroys glandular tissue There are acute inflammatory granulomas with marked histiocytic pattern with a predominantly lymphocytic infiltration within them the confluence of histiocytes forming multinuclear *plasmodia*

The second type preferably studied in parotids with accompanying gland biopsy, is a lesion carried through the lymphatics or by direct progression There almost always exists a large inflammatory focus poorly defined surrounded by an unaltered gland In the midst of this there are found leishmanias in reduced numbers as in the lacrimal gland

The *chagasic sialoadenitic lesion* is not the same as a bacterial lesion since only the cortical part is involved the center of the gland remaining undamaged This lesion also differs from tuberculous sialoadenitis by reason of the existence of polymorphonuclear leucocytic inflammatory elements by the absence of caseation by the presence of histiocytic follicles surrounding the giant cells and finally by the presence of leishmanias

Skeletomuscular—*Acute parasitic myositis of Chagas' disease* while frequent in animals is nevertheless rather difficult to verify in man In biopsy of muscle in the first period of Chagas disease there have been found rather regularly foci of necrotic myositis In this are seen fibers infiltrated at times with *polymorphonuclear cells at times with lymphocytes and plasmocytes* exceptionally with giant cells in the midst of healthy muscle tissue The invaded muscle segment undergoes necrosis or shows fragmentation These foci correspond to foci or zones of residual infiltration this in turn corresponding to primary parasitic myositis

Even though the muscle biopsy (punch biopsy) does not from the viewpoint of parasitology constitute definite diagnostic proof it does form a basis for a valuable anatomicopathologic estimate for recognition of the nature of the disease since there are no other affections which form such limited foci of monocellular alteration

The so called chagomic zone is generally surrounded by a wide hard elastic edema which does not pit on pressure

In the center of this ligneous area there may be a reddish hemorrhagic point with rose colored margins The erysipeloid outer surface of the chagoma generally shows a thin *furfuraceous desquamation*

With infants up to 1 year of age demonstration of *T cruzi* in the blood offers no difficulties and assures the diagnosis *In older children adolescents* and adults finding the trypanosomes by microscopic examination is more difficult and requires repeated periodic examinations for several days

Fig 60—Right temporal *chagoma of inoculation* with edema of both eyelids and the corresponding half of the face tenth day of development

If the examination of the blood gives negative results and if splenomegaly and more constantly hepatomegaly are present as well as definite signs of myocarditis as seen in the cardiac shadow upon teleroentgenography especially of the left ventricle with disappearance of the first sound in the mitral area and intermittent pulse one should resort to other diagnostic measures such as *xenodiagnosis* and *inoculation of blood* into white rats Both procedures however require a minimum of twelve to twenty five days before definite results become available

In difficult cases the differential count aids greatly in the diagnosis especially when there is a high *monocytosis* in children or a very high *lympho*

Lesions of *meningochoroido corticoencephalitis* are much the same as lesions of encephalitis in trypanosomiasis africana But lesions of chagasic corticoencephalitis are more frequent with many parasites present (leishmanias) In the vascular endothelium of venules and in perivascular cells leishmania forms are found (Mazza and Jorg) These are also present in nodules in the midst of nervous tissue In these nodular formations microglia cells as well as leucocytes intervene

As for *chagomas of inoculation* tumor like lesions from the cutaneous entry of chagasic infection these present histologically characters of most intense erosive pseudoulcerous dermoepidermitis with hypodermic *cytosteatonecrosis*

Metastatic chagomas appearing in the neighborhood of the chagomas of inoculation as if there existed a multicentric process of cutaneous tumor like manifestations are located in the skin with *inflammatory cytosteatonecrosis of* subcutaneous cellular tissue

Hematogenous chagomas are of the nature of cellulitis or dermatic hypodermatitis of hematogenous origin with different apearance in respect to tumor like phenomena of inoculation These chagomas histologically show cellulitis with *cytosteatonecrosis* Extension of the inflammatory lesions to the dermis is slight One variety of these chagomas is the *lipochagoma* (Mazza Freire) which is a localization of the trypanosomic inflammation in the adipose tissue of the cheeks In these cases the profound cellulitis of hematogenous character is histologically always inflammatory cytosteatonecrosis

SYMPTOMATOLOGY AND CLINICAL FORMS OF THE PRIMARY PERIOD OR FIRST STAGE OF THE DISEASE

In the first stage or primary period Chagas disease may or may not present external signs The most common external manifestations are as follows

1 Chagomas of Inoculation (Mazza) also called Cutaneous Glandular Complex (G and R Basso)

These may occur in any part of the body but they are seen most frequently about the head and face especially the forehead the neck the cheeks and the lip They are characterized by plaques of peculiar pasteboard like hardening of the skin not pliable generally hot and red which appear as if etched into the skin When formed in the abdominal wall and thighs these chagomas may assume large proportions They then cause hard ligneous infiltration which makes it impossible to bend the lower limbs They cause great pain There is generally multiple adenopathy with one very large gland predominating There is an elevation of temperature usually high in infants A sign of major diagnostic importance is tachycardia out of all proportion to the fever and fever may even be absent General malaise exhaustion osteo muscular pains and sometimes epistaxis and chills together with insomnia and restlessness and in nursing children continuous crying may occur either simultaneously or successively as manifestations of the *chagoma of inoculation*

cytosis at other ages accompanied by a more or less marked eosinophilia This may occur in the first stage or primary period

The chagoma of inoculation if left alone progressively disappears usually in two or three months Brown pigmentation which persists at the site of the lesion is most characteristic *There is atrophic retraction of the* skin the latter remaining adherent to the deeper planes of the chagoma as if fixed by *fibrous bands due to disappearance of the underlying fatty tissue*

Fig 63 —Left antebrachial chagoma of inoculation *I* and metastatic chagomas in left axilla *(arrows)*

and even of the smooth and striated muscles This effect is more perceptible when the chagoma is localized in the cheeks for when Bichat s pad because of its contiguity is involved it gives rise to *genial lipochagoma* (Mazza and *Freire) of the affected side* The consequent cytosteatonecrosis causes a fibrous retractile formation of the lipophagic granuloma In hairy areas alopecia is observed after the disappearance of the chagoma

By metastasis the fatty pad of Bichat may be invaded on the side opposite the infected area

Fig 61 —Chagoma of inoculation in the neck of a 6 month old child sixth day of development

Fig 62 —Edema of left eyelids (ophthalmoglandular complex) in the patient shown in Fig 61 in the sixth day of the chagoma of inoculation Shows absence of conjunctival contamination

The conjunctiva of the affected sides remains unaffected in certain cases, in others there is intense injection and edema chemosis and marked epiphora Suppuration seldom occurs Empirical medication is of no avail Generally seromucous secretion glues the eyelashes together In well established cases where the conjunctiva resembles that of Parinaud's conjunctivitis granulation changes and inflammatory products can be noticed in both lids especially the lower

The lacrimal sac may in certain cases suppurate and give the appearance of dacryocystitis but only in Chagas' disease is it accompanied by fever general exhaustion especially by tachycardia which may occur even without fever

Fig 64

Fig 6

Fig 64 Left ophthalmoglandular syndrome or complex thirteenth day of development (front view)

Fig 65 —Chagoma of inoculation in the check giving an impression of left ophthalmoglandular syndrome This is a very common pseudopalpebroglandular complex. This complex is rarely observed in its pure form

This last symptom which denotes myocardial affection is the most important differential point by which to distinguish true Chagas' disease from various common conditions which may simulate it In very young children this symptom with bronchitis and a very severe diarrhea is very frequently found

Exophthalmia usually occurs in conjunction with unilateral and erythrochromic edema of the eyelids with or without deviation of the eyeball. This is very pronounced in some cases not reducible because of the orbital cellulitis clearly showing its endogenous origin

These *metastatic chagomas* appear also in regions that are more or less symmetrical with those of the chagomas of inoculation, and they, too, undergo necrosis and formation of scabs They may also be seen in cases which had previously shown an apparently initial ophthalmoglandular complex

But the important chagomas are those which we have designated as *hematogenous* They occur in patients without any previous outside portal of entry of infection They have a characteristic appearance especially in infants They are consistent, hard formations which can be palpated under the skin by skin compression, in some cases without change in color, or in other cases revealing erythematous zones, characteristically indurated, so that these areas are very tough, with loss of cutaneous pliability

These hematogenous chagomas generally disappear leaving no effects of a permanent nature other than damage to that part of the skin where they were situated They may become soft and form abscesses, giving the clinical impression of a septicopyemic state The abscesses may be located symmetrically

The chagoma of inoculation may run another course, namely, that of ulceration In such cases, the lesion is covered with melicerous crusts or scabs which, when removed, reveal a granular surface that bleeds slightly, displaying a marked analogy to the lesions of cutaneous leishmaniasis

These ulcerations generally heal in a short time even without treatment leaving, after two or three months, cicatrices which though appreciably small, are definite in size and usually hyperpigmented

2 Unilateral Palpebral Edema Ophthalmoglandular Complex (G and R Basso), Palpebrofacial Cellulitis (Mazza and Jorg)

This is a frequent manifestation attributed by some to entry of infection into the conjunctiva However, it often occurs in individuals with previous general infection of several days' duration it may also follow trauma of the orbital region (fisticuffs) In many cases, edema of the eyelids is due to chagoma of inoculation in this region, at the base of the nose, or in neighboring areas and this cutaneous inoculation does not apppear immediately

Again, there is the question of edema of both eyelids which in general, arises suddenly and is usually noticed by the patient on awakening in the morning In this condition there is a violet red or livid coloration of the ocular adnexa The edema is usually very firm and does not yield to pressure, it advances rapidly toward the cheek the base of the nose, and the temporal region and extends to the neck and down to the supraclavicular fossa

Generally it is not painful even on pressure, but it may be hot the skin over the eyelids usually shows a furfuraceous desquamation

The preauricular or pretragal gland of the affected side is usually swollen to a noticeable degree It may be as large as a pigeon s egg or an olive, with or without periadenitis, frequently accompanied by minor neighboring adenopathy These glandular enlargements are particularly noticeable in the submaxillary or parotid regions This with the edema, considerably alters the appearance of this area

eyelids which was originally unilateral now spreads Finally, anasarca may follow these original manifestations

But these edematous symptoms may also be found often without preceding phenomena or apparent signs of infection apparently arising from some unknown point of entry

Among the most frequent of these primary edematous manifestations may be mentioned edema of the scrotum common in male infants edema of the pubis and lower abdomen in female infants areas of edema in both legs and thighs edema which we have designated "grotesque" because of its appearance in midbody or in one limb only or on the forehead

Fig 66

Fig 67

Fig 66—Pronounced exophthalmia. Twenty-seventh day of development of chagoma of inoculation in the left upper lid

Fig 67—Anasarca in a girl who was considered fat by her parents With no known previous portal or entry

In all these cases after excluding the possibility of genuine kidney disease if macropolyadenopathy and hepatosplenomegaly are present and particularly if there are signs of myocardial disturbance revealed at times only by tachycardia especially with fever these should induce a search for *T cruzi* in the blood especially in those geographical zones known to be endemic regions of Chagas disease

CHAGAS DISEASE WITHOUT EXTERNAL MANIFESTATIONS

In addition to these definite forms of Chagas disease described above which suggest the diagnosis even to inexperienced workers or influence one to resort to proper microscopic examination there are other cases which re

In untreated patients *palpebral edema* like exophthalmia may persist for four or even seven months

Another valuable and striking symptom especially in patients with a pre existing ophthalmoglandular syndrome is *dacryoadenitis chagasica* (Mazza and Benitez)—a point to be remembered in summing up the diagnosis We have designated this as hyperplasia and congestion of the palpebral or ac cessory lacrimal gland It may be determined by elevating the external part of the upper eyelid with the fingers and having the patient look downward and inward

This symptom of dacryoadenitis chagasica is slow to disappear and often persists after the palpebrofacial edema and other signs present in the sec ondary conjunctival reaction have subsided

At times the unilateral edema of the eyelids shifts to the opposite side more rarely it may exist simultaneously in both eyes

At any rate in the absence of albuminuria in these last cases bilateral and other diffused pretragal or submaxillary adenopathy as well as tachy cardia hepatosplenomegaly and great exhaustion accompanied by somnolence and in infants by signs of meningeal irritation offer clinical evidence in the diagnosis of Chagas' infection

3 Schizotrypanides

This refers to skin manifestations of chagasic origin so designated be cause of their analogy to trypanides of sleeping sickness or trypanosomiasis africana In Chagas disease there are different types

(a) *Morbilliform* not accompanied by the same essential signs of genuine measles It does not spread to the face There are no high temperatures It is not contagious for other children Koplik s spots are absent Patients who have had measles may be affected and the sickness may appear at other than epidemic periods

(b) *Urticariform* generally not pruriginous followed by persisting zones of brown hyperpigmentation

(c) *Multiform erythematous* the outbreaks of various size located prefer ably on the anterior surfaces of the thorax and thighs rarely diffuse

(d) *Ulceration* which may appear late

All of these schizotrypanides may follow manifestations of this infection such as chagomas or the ophthalmoglandular complex or they may be followed by these last named symptoms They cause elevations of temperature at the time of eruption and may persist for several days disappearing finally with out complications

4 Localized Edema, Anasarca

This edema is very firm elastic without crepitation frequently follow ing chagomas of inoculation or the ophthalmoglandular complex It localizes in the legs and feet sometimes ascending to the pubic and lower abdominal regions The face usually remains swollen due to the fact that edema of the

ence of *T cruzi* is shown by its dancing movements scarcely moving out of the field of view This procedure is particularly useful in examination of nursing infants where generally a large number of parasites are found in the circulating blood In older children adolescents and adults diagnosis in this manner can be made less frequently

The *thick film* examination is of great value The film is stained with Giemsa stain without previous fixation In this procedure a dilution of one drop of stain for each cubic centimeter of neutral distilled water is placed on the thick film which has been dried in the air The erythrocytes are hemolyzed leaving the white blood cells blood platelets and the parasites properly stained

This test should be repeated periodically or every day making several preparations each time and examining each carefully *T cruzi* in the bloood can usually be demonstrated with this method Sometimes it is necessary to stain *five or six thick drop preparations* before arriving at a definite diagnosis

If this test fails to reveal the parasites it is necessary to rely on injection of 0 5 c c to 0 75 c c of citrated blood intraperitoneally into white rats If the result is positive trypanosomes will appear in the blood after a period of five to twelve days and sometimes after twenty to twenty five days

This method is to be used for relatively recent cases and for children For older patients with a longer development of the disease injection intraperitoneally of 5 to 10 c c of citrated blood is indicated Up to 20 c c of citrated blood can be conveniently injected intraperitoneally into puppies about 1 month old to demonstrate cases during the tertiary period especially cardiac cases Observation of these animals should extend over a period of three months with periodic examinations of the blood Even though the blood examination is negative a complete histopathologic examination of all the organs and skeletal muscles of the inoculated animal must be made

It should be noted that animals which do not show trypanosomes in the circulation during life may nevertheless present leishmanias of *T cruzi* either in the striated muscles or in the smooth muscles of the stomach and intestine or in the heart or even in the skin or subcutaneous cellular tissue (Mazza)

Xenodiagnosis

(See Chapter 72)

Biopsy

Biopsy of lymphatic glands with proof of leishmanias in the histologic section is a procedure which should follow those just explained namely the extirpation of the so called prefect gland Biopsy or punch biopsy of striated muscle is of little value because poor results are usually obtained in demonstration of leishmanias

Residual lymphocytic plasmocytic infiltration with giant cells in necrotic and fragmentary muscular segments may give well founded indications of Chagas disease even in the absence of parasites

quire the services of trained observers to recognize the possibility of their existence in endemic rural areas greatly infested by triatomas which harbor the developing forms of *T cruzi* In such cases, there is scant evidence of this infection, so that many of the cases may escape detection

Of importance in the diagnosis of all cases is the appearance of cardiac changes, especially alterations in rhythm, with lowering of arterial tension especially embryocardia in infants, or tachycardia of high frequency at other ages These signs and symptoms, together with hepatosplenomegaly and multiple adenopathy, should suggest an examination of the blood for *T cruzi*

With no previous external signs, the most important manifestation of Chagas' disease is *primary meningoencephalitis* It affects nursing infants exclusively and may be very serious, as a matter of fact, it is almost always fatal

We have used the term *primary* meningoencephalitis because this localization may also occur *secondarily* in the course of the disease with such initial manifestations as chagomas of inoculation, ophthalmoglandular complex, edema, anasarca, etc

Convulsions are usually solitary and infrequent in other cases, however, they are generalized, clonic or tonic and preceded by great unrest and persistent and inconsolable crying The convulsions at first are not of a serious character They later become more frequent of longer duration and often show a tetanic character, with opisthotonus repeated vomiting of the cerebral type, and constant crying

These clinical forms are of short duration, and in general death may follow *in less than a week Few survive this stage without due treatment* According to Chagas, such patients show serious nervous syndromes which probably, until Chagas described them, were thought to be the result of some other disease

Those who recovered under adequate treatment, as far as is known, showed no sequelae or residual effects of the invasion of the central nervous system

Forms that are simply primary febrile or which are accompanied by the typhoid or tuberculosis like state certainly are often overlooked in endemic regions

It is of great diagnostic importance in such cases to evaluate the temperature curve, for example, a rise of 2 or more degrees in twenty four hours, when the temperature is taken every three hours This phenomenon in which respect Chagas' disease resembles visceral leishmaniasis is not constant and may be replaced by a frank notching of the peak of the evening temperature rise in Chagas' disease, it is explained by the greater or lesser invasion of the organs by the leishmania forms of the parasite

ETIOLOGIC DIAGNOSIS

In all cases where Chagas' disease is suspected, it is essential to demonstrate the chagasic etiologic character of the disease This test can be made by direct examination of fresh blood between cover glass and slide Pres

appreciable clinical improvement (reduction of edema glandular enlargement decreased tachycardia cephalalgia fever restlessness somnolence), it is best to administer the drug only every other day or at two day intervals

For adolescent and adult males a minimum of 0 ?0 to 0 60 Gm per kilogram of body weight should be reached 0 20 to 0 40 Gm is used for women

In nursing infants especially those with the meningoencephalitic form it is necessary to arrive at and to administer as quickly as possible a minimum dosage of 120 to 1?0 mg per kilogram and even more than this amount according to the severity of the case

It is desirable to repeat the administration of 7602 (Ac) *(Bayer)* or M 3024 *(I C I)* after a short period of rest 7602 (Ac) *(Bayer)* and M 3024 *(I C I)* have no action against other trypanosomes *9736 (As) (Bayer)* has been used in Chagas disease by Mazza with good clinical results

Dosage of 9736 (As) (Bayer) is as follows for children doses of 15 c c up to a total of 30 c c for male adults 50 c c and women 40 c c total doses are given

Sodium penicillin shows pronounced clinical action in doses of 20 000 to 30 000 Oxford units per kilogram of weight It is given intramuscularly in injections of 10 000 to 20 000 units every three hours Its trypanocidal effect however is low

In every case the patient is to rest preferably in bed confined to his home and must avoid hard work that may adversely affect the action of the heart

If cardiac tonics are necessary they are to be used with caution Administration of vitamins especially of the B group (thiamine hydrochloride) intramuscularly and in appreciable dosage is more beneficial Liver extract especially with vitamin B or even used alone causes improvement many times in the majority of patients In addition this therapeusis favors greater toleration of other drugs

Certain arsenicals such as cacodylates Sulfarsenol neoarsphenamine arsphenamine Acetylarsan Pirossyl (Stovarsol) *may be conveniently used* for although they lack specific action against the disease they have a general tonic effect stimulating the reticuloendothelial system and they also act upon a concomitant hereditary or acquired syphilitic lesions

When these drugs fail water soluble salts of bismuth may be used administered as for syphilis

PROPHYLAXIS

Prophylaxis consists in avoiding contact with vinchucas or kissing bugs" as the triatoma transmitters are called Since these breed in primitive or lowly dwellings it is through construction of adequate housing that the vector will eventually be exterminated a very difficult problem in sparsely populated regions or in districts with great poverty

The complement fixation reaction or the Guerreiro Machado reaction, applied to Chagas' disease, with serum of the patient in the presence of aqueous extract of liver from a puppy which has died of the disease, gives results of great presumptive value It is particularly indicated in the secondary and tertiary periods of the disease While the test may be positive, it still does not entirely exclude the necessity of inoculating the patient's blood into susceptible animals, nor does it exclude the use of xenodiagnosis

These tests as well as cutaneous and intradermal tests by themselves do not assure a definitive diagnosis of Chagas' disease They may simply indicate an old infection by *T cruzi* This is not unusual in localities where often all the inhabitants have overcome the chagasic infection at one time or another

TREATMENT

In our experience medication which has proved efficacious against other forms of trypanosomes has had no effect against *T cruzi* Various arsenicals have been tried, one after the other without success notwithstanding the fact that they are effective against other trypanosomal infections in man and in lower animals

In 1936, a preparation known as *7602 (Ac) (Bayer)* was developed by Jensch of Leverkuffen The composition of this drug a *quinoline derivative,* was described by Curd in England in 1945 (Mazza 1945) It is a *sulfate of diallyl malonyl diamide of 2 methyl 4,6, diamino quinoline*

Curd also synthesized a product called *M 3024 (I C I)* Fulton (1943) showed experimentally the similarity of its effects with the original German drug Mazza showed that *M 3024 (I C I)* has the same action and clinical efficacy as *7602 (Ac) (Bayer)* This substance mixed with twice its weight of urea, is used as a solution prepared at the time of use It is made by dissolving 0 15 Gm of sterile powder, which is kept in sealed ampules in 5 c c of doubly distilled water (3 per cent) and is injected intramuscularly deep into the buttocks, using a fine needle

The injection causes pain Greater dilution does not prevent pain nor does it avoid discoloration at the site of injection persisting for one or two days

Following each treatment there is frequently a rise in temperature There also develops unrest and malaise in addition to a brief increase in external symptoms in the twenty four hours following the first injection

Injections may be repeated daily in the referred dosage of 0 15 Gm and may even be doubled or tripled (0 30 Gm or 0 45 Gm in 10 c c or 15 c c of water respectively), always preceded by a test for albumin in the urine If albumin is present it is desirable to wait until it disappears, if however, the injection is urgently needed, the size of the dose may be decreased

In general after albuminuria disappears it does not reappear when treatment is resumed provided there have been four or five days of rest After

CHAPTER 9

AFRICAN SLEEPING SICKNESS

Oscar Felsenfeld

Sleeping sickness or African trypanosomiasis is often designated as "African sleeping sickness," to distinguish it from Economo's lethargic encephalitis which also formerly was called "sleeping sickness." It is a disease caused by trypanosomes and is characterized by chronic fever, more or less intensive glandular enlargement, and, in many cases, a cerebral stage with fatal outcome.

GEOGRAPHY

The geography of sleeping sickness follows the African belt of the tsetse flies (Glossina), mainly of *Glossina palpalis*, *Glossina tachinoides*, *Glossina morsitans*, and *Glossina swynnertoni* which are the most frequent insect vectors of the disease. The northern boundary of sleeping sickness today approximately follows a line drawn from St. Louis to the Lake Chad, then along the Shari and the southern part of Anglo-Egyptian Sudan. Abyssinia and Italian Somaliland are free from it. South West Africa and the Zambezi River, with the exception of two foci, are the southern boundaries, while in West Africa, along the Gulf of Guinea, in the Congo, in Angola, Sudan, Uganda, and Kenya, the classic type ascribed to *Trypanosoma gambiense* prevails and the Rhodesian type ascribed to *Trypanosoma rhodesiense* is found in Tanganyika, Mozambique, Nyasaland, and Rhodesia.

Etiology

Sleeping sickness is caused by trypanosomes. These organisms are very similar to *Trypanosoma brucei*, the agent of the animal disease "nagana." Two types of trypanosomes have been described as the cause of sleeping sickness: *T. gambiense* and *T. rhodesiense*. It is not possible to differentiate between these types morphologically or by animal experiments, except by production of keratitis in goats by *T. rhodesiense*. It was formerly believed that the forms of *T. rhodesiense* in the blood of injected mice or rats more frequently have their nuclei located more posteriorly than do forms of *T. gambiense* under similar experimental conditions. Some authors consider *T. rhodesiense* a human-adapted variant of *T. brucei*. Others ascribe the difference in clinical types of sleeping sickness to the adaptation of the trypanosomes to different species of Glossina.

The organisms appear irregularly in the blood but are usually present during the periods of fever. They are most easily found in enlarged lymph glands, later occurring in body fluids, principally the cerebrospinal fluid. Aside from elongated, slender trypanosomes, rather short, broad forms with smaller flagella and posterior nuclei may be observed. After the organisms enter the tsetse fly by feeding on a patient who harbors trypanosomes, they multiply in the mid gut, later in the hind gut, of the Glossina. After twelve to thirty six days, depending on temperature, humidity, and other factors, the infective metacyclic forms reach the salivary glands of the fly and may be injected into a susceptible host during a blood meal.

Trypanosomes of sleeping sickness are difficult to cultivate. They are, however, easily transferred to laboratory animals, chiefly to mice, rats, and guinea pigs.

As to personal hygiene, one should avoid placing bedding on the floors or having beds against the walls Sleeping with mosquito netting stretched well away from the body and with the lights kept burning are also highly recommended

to step on thin roots *T. rhodesiense* is found in the waterbuck *(Kobus ellipsoprymnus)* reedbuck *(Redunca arundinacea)* and duikerbok *(Cephalophus grimmi)* Cattle goats sheep and even pigs have been found to harbor trypanosomes

RESISTANCE

There is no racial predisposition to sleeping sickness Neither does the disease prefer people of one sex or of a certain age group Those who live near rivers or spend time working or travelling on inland waters are more exposed to the bite of tsetse flies and, therefore fall prey more easily to sleeping sickness

Trypanosomes as a rule are not transferred from the mother to the fetus Exceptions however have been described

There may be a certain degree of immunity among people who live in territories which have been infested for a long time Manson Bahr (1915) emphasized that sleeping sickness is less virulent in West Africa where it has been present for a very long time while in the newer foci of Uganda the course is more severe Due to the lack of partial immunity the disease is more acute in white men than in natives The Rhodesian form, however, is generally acute both in whites and in natives

PATHOLOGY

The bodies of patients who have died of African sleeping sickness are emaciated Since this is due to lack of nourishment the organic findings are with the exception of the central nervous system and the lymphatic apparatus rather meager

The skin may show edema which as a rule is confined to the face and the perineal region The back is less often involved The disease is principally an affection of the lymphatic system so that lymphatic infiltrations are often found in the skin

The lymph glands particularly of the neck of the mesentery, and of the groins are enlarged There is increased production and proliferation of the lymph cells The glands appear vascular In addition to the lymphocytosis monocytes are often found

The brain shows changes resembling those found in general paresis There is a chronic meningoencephalitis and a meningomyelitis The changes in the brain predominate The vessels are contracted Endarteritis with endothelial proliferation causes thickening of the vessels The perivascular space shows round cell infiltration Lymphocytes, neuroglia, and more or less modified plasmocytes form the infiltrate When perivascular infiltrates attain considerable width, they are called "coat sleeve" or "cuff"

The surface of the brain shows flattened convolutions and shallow sulci The brain tissue is edematous The ventricles are dilated by the pressure of the increased amount of cerebrospinal fluid The Rhodesian types show little changes in the brain

The cerebrospinal fluid contains many mononucleated cells such as lymphocytes, monocytes and plasmocytes Eosinophiles may also be present Trypanosomes can be found in many cases The total number of cells is 50 to 5,000 in fatal cases There is a great increase in the protein content, which may be higher than 1 5 Gm

VECTOR AND ANIMAL RESERVOIRS

The trypanosomes are usually transferred by tsetse flies after they have gone through a cyclic evolution in these insects There is, however, a possibility of purely mechanical transfer by Glossinae and other biting insects from person to person under certain circumstances

The principal species of Glossina which transfer sleeping sickness are *G palpalis* and *G tachinoides* for *T gambiense*, *G morsitans* and *G swynnertoni* for *T rhodesiense*

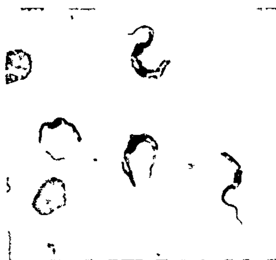

Fig 68 —*Trypanosoma gambiense* in peripheral blood

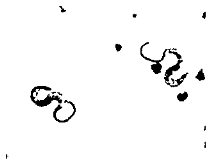

Fig 69 —*Trypanosoma rhodesiense* in peripheral blood

Most species of Glossina require shade and proximity of water *G palpalis* prefers human blood, while *G tachinoides* is impartial in its feeding habits *G morsitans* and *G swynnertoni* feed mostly on cattle and antelopes *G morsitans* is attracted by individuals, animals, and objects and will follow a running person or antelope for hundreds of yards

Glossinae which live in southwest Arabia are not infected with trypanosomes It is also worthy of note that the organisms are not transferred to the larvae of the flies

No repellent effective against tsetse flies is known

Of the animals naturally infected with *T gambiense*, the best known is the marsh inhabiting sitatunga (*Limnotragus spekei*), a shy antelope with highly cleft hoofs enabling it

Glomerulonephritis is not rare The spleen is not considerably enlarged There is round cell infiltration The number of Malpighian bodies is reduced As a rule the liver is not enlarged Pericardial, pleural and peritoneal effusions are common in the Rhodesian form

The heart shows round cell infiltration and degenerative changes Very intensive inflammatory alterations are common in the Rhodesian type The lungs may show proliferation of round cells The bone marrow shows regressive changes

Because the immediate cause of death is some intercurrent disease such as pneumonia malaria tuberculosis dysentery etc the autopsy findings are often *dominated by the changes caused by the terminal complicating sickness*

INCUBATION PERIOD

The incubation period is very irregular An incubation of ten to twenty one days is very often observed, *frequently, however, it is far longer* According to some authors the incubation period may be as protracted as several years

SYMPTOMATOLOGY

Classical Type

The initial phenomenon is the so called trypanosome chancre This consists of a red nodule surrounded by a pale zone The nodule is slightly elevated and attains a diameter of one half to one inch Its site is the place of the bite of the tsetse fly After a few days usually after three the nodule disappears leaving a slightly pigmented spot which may be visible in white patients for a few weeks

The first general symptom is the initial fever which develops one week or later after the initial chancre It is irregular, intermittent and remittent *courses are observed* While the morning temperature is normal or slightly subnormal the evening temperature may reach 103° to 104° F The decline of the fever is rarely accompanied by the usual sweating of such states

The pulse rate and the respiration rate increase with the height of the fever The patient complains of headache Neuralgia is often present The nerves of the extremities and of the head are most often involved *The pain* may be continuous or it may appear in attacks of varying intensities

A rash composed *of pinkish circinate nummular erythematous* skin lesions is observed in white patients The rash is often accompanied by pruritus and edema In the native population the erythema is scarcely visible because of the dark skin This rash disappears after some time

Trypanosomes appear in the blood during this period of the disease They are more abundant during the fever periods

Kerandel's sign is of much diagnostic value during this stage of the sickness This sign is based upon *the development of deep hyperesthesia* especially over the ulna A slight impulse which under normal conditions

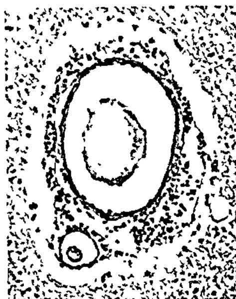

Fig 70 —Perivascular infiltration in the brain in sleeping sickness

Fig 71 —Meningitis in sleeping sickness high power

Very often the patient does not speak at all if not questioned The gait is deliberate and slow, as are the other movements Later the patient is scarcely able to keep awake and falls asleep even while eating There is loss of control of saliva urine, and stool

The habits of the patient deteriorate He becomes negligent and unclean Delusions and mania are often observed

Debility is a constant development *The facial expression reflects the* psychologic state It is dull and vacant The eyelids are lowered The lower lip begins to hang Saliva drips from the corner of the partly open mouth

The neurologic symptoms are governed by the localization and extent of the cerebral and meningeal lesions Headache, usually dull frontal or occipital pain rarely migraine like attacks is the rule Convulsions may be present Paralysis of nerves or groups of nerves is not uncommon

Fibrillary twitchings of the tongue and of the muscles of the arm are early symptoms of the cerebral stage Tremor of the tongue of the fingers and of the upper extremities rarely of the legs is very frequent from the beginning of sleeping sickness

Pruritus is a regular symptom causing scratching with subsequent skin infections

The knee jerks are increased in the beginning later decreased All reflexes are decreased during the later stage of the sickness

Because of the diminished ability of the patient to feed himself cachexia develops Symptoms of avitaminosis skin lesions and decubitus are very frequent

The cause of *death is an intercurrent disease as pneumonia dysentery or* injury also attack by animals mainly when the patient during a maniacal outburst runs away into the jungle and because of his sickness cannot protect himself adequately

Rhodesian Sleeping Sickness

As stated above in the pathology of African sleeping sickness the Rhodesian form shows more visceral and fewer cerebral changes

The symptoms are similar to those of the classic or Gambian type *The* Rhodesian form is more acute The fever is usually higher and there are fewer remissions and intermissions Trypanosomes are numerous in the *peripheral blood The rash is very frequent and of long duration Edema* develops more frequently and is usually extensive

There is little or no enlargement of the lymphatic glands On the other hand disturbances of the cardiovascular apparatus are pronounced Tachycardia is a constant symptom *Later irregularity of the heart action develops*

Convulsions occur very often Mania is frequent

Because of the rapid course of the disease cachexia develops within a relatively shorter time Death occurs within six to twelve months after the onset

Abortive Forms

Persons without history of typical African trypanosomiasis but apparently exhibiting an immunity against the *disease are often found in*

would cause only the feeling of touch evokes delayed pain Often the patient himself complains of unusual pain caused by small impulses

Later the fever decreases but returns after shorter or longer periods of intermission The recurring febrile attacks may be mild or severe The fever may reach various levels but the temperature is always higher in the evening Continuous fever has also been observed

The lymph glands become enlarged The enlargement is most apparent in the cervical glands Winterbottom s sign consists in the observation of enlarged lateral neck glands when the patient turns his back to the examiner The glands are soft but later become very hard They are usually painless but may be tender on palpation When secondary infection is absent they do not suppurate

The spleen is usually enlarged and soft during this period The liver also shows enlargement

The patient often has cramps and paresthesia of different locations and intensities

Persistent tachycardia irritability headaches and insomnia are usual complaints

Manson Bahr (1945) points out the importance of erythemas composed of fugitive patchy annular or irregular rings mostly on the trunk They may be of irregular size and shape and often become huge They fade into the surrounding skin These erythemas are evoked by irritation of the skin by different factors such as heat They are often accompanied by edema

Of great importance are the ocular disturbances Iridocyclitis and chorioiditis are not uncommon Such eye lesions when not diagnosed may develop into serious consequences during treatment with arsenicals

The patient loses weight Anemia develops

This stage of sleeping sickness characterized principally by enlargement of the glands irregular recurring and intermittent fever enlargement of spleen and liver may last for a long time even for years Then either spontaneous cure follows or the cerebral stage begins

Sleeping Sickness Proper

The disease has received its name from the clinical symptoms that accompany this stage also called the cerebral stage " because the psychoneurologic changes induced by the developing brain pathology dominate the picture during it The cerebral stage represents the terminal period of the disease and ends with death It may be acute or chronic It lasts usually three to eight months A more extended duration of sleeping sickness as long as one year has also been recorded

As a rule sleeping sickness proper begins slowly The patient becomes somnolent Desire to sleep during the daytime is usually the first symptom of the onset The intensity of the somnolence gradually increases The patient falls asleep anywhere and in every position If not asleep his actions are lethargic Speech becomes slurred Questions elicit late and retarded answers

Serologic Reactions

Serologic reactions described for the diagnosis of African sleeping sickness are numerous The so called adhesion reaction is sometimes utilized for diagnostic purposes This phenomenon consists of the adhesion of human red blood cells to trypanosomes when trypanosomes are mixed with immune serum complement and red blood cells In the presence of a nonspecific serum no such clumping or adhesions occurs Serologic reactions however have not as yet attained an important place in the diagnosis of sleeping sickness

Clinical Pathology

The blood picture shows secondary anemia The number of white blood cells is within normal limits in the beginning of the disease Leucocytosis appears during the later stages of sleeping sickness There is a relative increase of lymphocytes and of monocytes

Autoagglutinins occur very often causing rouleaux formation of the red blood cells Cold agglutinins have not been found

The blood sugar and the alkali reserve of the blood decrease during the disease The serum is depleted of proteins chiefly of the albumin fraction The albumin globulin ratio is low Nonprotein nitrogen urea and creatinine increase in the terminal stage while the amount of cholesterol usually decreases

During the cerebral stage the spinal fluid contains many cells mostly lymphocytes and plasmocytes The occurrence of plasmocytes in the cerebrospinal fluid is of diagnostic value

As a rule a considerable amount of globulin is present in the spinal fluid The reactions of Pandy Nonne Apelt and Weichbrodt are positive The gold curve shows the paretic type

DIFFERENTIAL DIAGNOSIS

African trypanosomiasis must be differentiated from other generalized infectious diseases such as virus encephalitis malaria leishmaniasis syphilis and leprosy from cerebral and meningeal disorders such as brain tumors general paresis and from pellagra late beriberi and Hodgkin s disease

The differential diagnosis is greatly facilitated by gland puncture if the lymphatic glands are enlarged by the examination of the cerebrospinal fluid and by the search for trypanosomes in the peripheral blood The examination of the bone marrow (sternal puncture) is very helpful

PROGNOSIS

Except for the abortive cases the prognosis is serious in all clinically manifest cases which have not been treated Spontaneous healing is possible but not the rule When the cerebral stage sets in not even intensive treatment can save a great number of the patients

endemic regions The search for abortive infections was intensified when during surveys of the population in infested regions trypanosomes were recovered from the peripheral blood of individuals who did not show classical symptoms Further studies revealed that abortive cases are not rare

There may or may not be an initial rash Low grade fever of irregular character often remittent or intermittent for a few days or weeks is present There is headache and general malaise When one considers that such symptoms may occur in the tropics for a number of reasons it can be easily understood that they may be misinterpreted particularly if means of laboratory examination are inadequate

LABORATORY DIAGNOSIS

It is necessary to keep in mind that the number of parasites in the peripheral blood undergoes considerable fluctuation The parasites are moreover not easily recovered from the cerebrospinal fluid in every case Gland puncture is therefore the method of choice for recovering the parasites if there is enlargement of the lymphatic glands

The Peripheral Blood

Cultivation of the trypanosomes is not as yet so simple that it can be used as a diagnostic method

For animal inoculation guinea pigs are used most often Five or 10 c c of the blood are injected intraperitoneally

Microscopic search for the trypanosomes in the peripheral blood is carried out with the aid of the thick drop method or citrated blood is well centrifuged and the sediment examined

Both unstained and stained preparations are observed For staining the Giemsa method and its modification by Field are recommended *

The Lymph Glands

The lymph glands are punctured after massage using a relatively strong needle and a 10 or 20 c c syringe Smears are prepared and then stained with the Giemsa or Field method While strict asepsis is necessary for this operation no anesthesia is needed

The lateral cervical glands are easily accessible particularly when they are enlarged Massage of the glands during puncture enhances the operation Unstained and stained smears are examined

Cerebrospinal Fluid

The cerebrospinal fluid must be centrifuged in an examination for trypanosomes The sediment can be observed under the microscope injected into guinea pigs or used for cultivation Trypanosomes are often recovered from the fluid gathered through suboccipital puncture and also from sternal puncture material

*See Chapter 63

The best known remedies of African sleeping sickness are tryparsamide and Antrypol

Tryparsamide (Novatoxyl Tryparsone Glyphenarsine) is sodium N phenyl glycine amide p arsonate It is used both in incipient and in cerebral cases It may be injected into the muscles (usually in 10 to 20 per cent solution) The medium dose is 80 mg per kilogram of weight (Manson Bahr) the total dose for one series of injections is 24 Gm Some workers however advocate a total dose of 60 to 100 Gm

According to one schedule three injections are given every week using first 10 c c then 20 c c of a 10 per cent solution These injections are continued for a length of time corresponding to the severity of the disease In advanced cases the following amounts of a 20 per cent solution are injected 3 c c on the first day 6 c c on the fourth and 10 c c on the eighth day then beginning with the twelfth day 12 c c every four days until twenty injections have been given This treatment is repeated after a three month intermission

Another scheme recommends one injection every week first 1 to 1 5 Gm then 2 to 3 Gm according to the weight of the patient A total of fifteen injections is given

Children receive doses up to 80 mg per kilogram body weight for twelve injections

Kellesberger (1943) advocates doses of 45 mg per kilogram of weight a total of 30 to 50 Gm The injections are given once a week If necessary, the series is repeated one to three months later Kellesberger recommends a test injection chiefly in advanced cases Twelve milligrams of the drug per kilogram of weight are injected for this purpose If no untoward reaction is observed the Tryparsamide treatment may be used

Fowler (1945) found that massive doses given by the intravenous drip method are very effective The patients must be hospitalized for this therapy The time of hospitalization is about two weeks Only children and young adults may receive this treatment

Optical neuritis is the most dangerous side effect of the drug The excellent therapeutic results observed in thousands of cases however counterbalance this undesired complication

Antrypol (Belganyl Moranyl Suramin B P Bayer 205 Fourneau 309 Naphuride) is given intravenously in a 10 per cent aqueous solution The total dose is 10 Gm

According to one schedule every fourth day 5 c c, later 10 c c are given until the total dose has been administered

The second scheme calls for the injection of 10 c c on the first third tenth and thirteenth days Then the same dose is repeated once a week In advanced cases doses of 15 c c and even 20 c c have been recommended

Antrypol however is not effective in the cerebral stage of African trypanosomiasis Toxic dermatitis and kidney irritation are observed After a few injections some protein and yellow colored granular casts occur in the urine The appearance of the casts is due to the excretion of the drug through

TREATMENT

The Belgian French and British governments have spent enormous sums for the eradication of sleeping sickness Today when the native populations have learned the advantages of proper medical care the efforts of the colonial agencies are focused on the desire to have every infected person receive a regular course of treatment It has been observed that interrupted or otherwise irregular therapy causes the appearance of drug resistant trypanosomes

The development and nature of drug resistance by trypanosomes is not known It is possible to prove with the aid of microchemical reactions or by the use of fluorescent light that resistant trypanosomes contain less arsenic than the nonresistant forms Eagle and Magnuson (1944) discussed the theories which attempt to explain the origin of drug resistance This coincides with the degree to which arsenic is bound by the trypanosomes Presumably the cell membrane of the organism becomes less permeable to the drug

If a strain of trypanosomes becomes resistant to arsenic it usually does not revert to the arsenic sensitive type with ease When arsenic resistant trypanosomes are picked up by a tsetse fly and transferred to another individual the organisms retain their resistance against arsenic even after passage through the Glossina In other words an arsenic resistant strain may be propagated This phenomenon causes difficulties in the therapy of subsequent cases of infection which cannot be avoided under present conditions Proper treatment is therefore necessary not only for the sake of the patient himself but also for epidemiologic reasons even to a greater extent than in many other communicable diseases

The treatment of African sleeping sickness with arsenic preparations dates back to Ehrlich who dreamed of a *therapia sterilisans magna* possibly through one single injection of an effective drug His first compound Atoxyl however proved to be very toxic The most feared effect of this and other trypanocidal drugs is optic neuritis Ocular lesions in trypanosomiasis were recently studied by Ridley (1945) It seems that diseases of the eye are not rare in sleeping sickness and that numerous drugs aggravate an already present ocular lesion rather than cause a pathology *sui generis* In order to avoid this complication it is essential to examine the eyes periodically with the aid of a slit lamp and an ophthalmoscope during the treatment A very important method of eye examination is to show the patient small objects If even slight impairment of the vision is apparent the administration of the drug must be stopped immediately It must be realized that ocular lesions often develop some time after the treatment has been completed The relatively new aromatic diamidine compounds such as Pentamidine (diamidinodiphenoxy pentane) Stilbamidine (diamidinodistilbene) and Propamidine (diamidinodiphenoxy propane) do not cause ocular lesions but lower the blood pressure As a result of this action many patients suffer collapse The blood pressure however rises again in about one half hour after the injection No fatal incident or permanent damage following the administration of these drugs has been described as yet

General Treatment

Any person who harbors trypanosomes in his body or shows signs of African trypanosomiasis should be isolated in a well screened house The diet must be mixed rich in vitamins Injections of vitamins C and K and of the B complex vitamins are beneficial

When the cerebral stage has already developed, proper nursing care is of utmost importance The patient must be fed Adequate cleanliness must be assured When mental disturbances are present the patient constitutes a real problem in many localities because of the lack of proper psychiatric care and facilities in the rural tropics

Spinal punctures are beneficial No patient should be dismissed before the findings in the cerebrospinal fluid become normal The spinal fluid should be re examined every three to six months for two consecutive years after the clinical cure

Skin lesions and neurologic symptoms are treated according to the established rules of proper medical specialties

No therapy of the optic neuritis is known to date Other ocular lesions are treated in the usual manner

PROPHYLAXIS

Chemoprophylaxis — An injection of 1 Gm Antrypol or Tryparsamide every three to six months is said to protect against African trypanosomiasis

Individual Prophylaxis —The tsetse flies bite during the day Therefore one should travel only during the night in infested areas

The breeding places of the Glossinae must be avoided

Proper mosquito netting is very important

Public Health Measures —Dispersion of the tsetse flies must be prevented Careful control of airplanes coming from areas inhabited by Glossinae has been established and seems to be effective

Removal of the entire population from the endemic area as carried out in Uganda is a good but not always practical measure

Excellent results have been obtained by cleaning the bush and undergrowth at least thirty yards from the water edge, thus destroying the breeding places of the tsetse flies

DDT smoke has been found effective for small foci

Fly traps have been given many trials Not all species of Glossina are however attracted and caught by them

So called fly boys have been used successfully They carry nets and catch tsetse flies

the urinary system Casts may be found in the urine for about one week after the end of the treatment Neuritis is also ascribed to Antrypol therapy

Diamidine compounds are given in doses of 0 5 to 2 mg per kilogram of body weight in daily injections for thirty days Some workers administer them for a period as long as ninety days Pentamidine is given intravenously Stilbamidine and Propamidine are injected into the muscles or into the veins Propamidine is little used

Stilbamidine has been found to be very effective in the mouse test by Fulton and Yoke (1943) but according to clinical reports other drugs are more effective

Pentamidine was recently tested by van Hoof et al (1944) and was found reliable even for prophylactic use Lourie (1942) Harding (1944) and Saunders et al (1944) agree that this drug must be used only in early cases when the white cell count in the cerebrospinal fluid is still low Harding recommends Pentamidine when fewer than 15 cells per cubic millimeter are present in the spinal fluid while Saunders et al were successful in cases having even as many as 30 cells per cubic millimeter in the cerebrospinal fluid This drug is definitely less toxic than Antrypol or Tryparsamide It must be injected very slowly in order to prevent a sudden drop of the blood pressure which occurs in a number of patients

Among other recently developed drugs Melarsen oxide and 70 A have been found very effective by Weinman and Franz (1945) Recently Melarsen B 2 to 4 mg per kilogram per day in short series has been tried

Combined Treatment

If the treatment with one drug is not effective or when relapses occur another remedy should be chosen Trypanosome strains may be resistant to certain drugs While this resistance is often a result of adaptation to a drug after treatment chiefly arsenicals naturally resistant strains also occur Harding (1945) found that Tryparsamide resistant cases react well to a combined treatment with Tryparsamide and Pentamidine

For combined Antrypol and Tryparsamide treatment Manson Bahr (1945) recommends injections of large doses of Antrypol then twice a week 2 Gm of Tryparsamide or in three to four day intervals 1 5 Gm Antrypol and then after a ten to fourteen day intermission six to eight weekly injections of Tryparsamide 70 mg per kilogram weight for a child 55 mg per kilogram weight for an adolescent and 45 mg per kilogram weight for an adult

Another effective combination is the use of alternate injections of Antrypol and Tryparsamide in three day intervals

Harding (1944 1945) obtained favorable results with concurrent daily injections of 100 mg Pentamidine and 2 Gm Tryparsamide for five consecutive days In more advanced cases however Antrypol and Tryparsamide must be used simultaneously

CHAPTER 10

LEISHMANIASIS, CUTANEOUS, MUCOCUTANEOUS, AND VISCERAL, WITH SPECIAL REFERENCE TO ITS OCCURRENCE IN THE AMERICAS

SAMUEL BARNSLEY PESSÔA

INTRODUCTION

Leishmaniasis is a disease caused by flagellate protozoa of the genus *Leishmania* Ross 1903.

There are three species of the genus Leishmania which parasitize man, all of which are *morphologically identical*.

1. *Leishmania donovani* (Laveran and Mesnil, 1903), which causes visceral leishmaniasis, kala azar, *infantile leishmaniasis of the Mediterranean area, and* the American kala azar or American visceral leishmaniasis.

2. *Leishmania tropica* (Wright, 1903), *which causes cutaneous* leishmaniasis known also as Oriental sore, Biskra button, Baghdad boil, Delhi boil, Lahore sore, Aleppo boil, etc.

3. *Leishmania braziliensis* (Vianna, 1911), which causes leishmaniasis americana or mucocutaneous leishmaniasis, espundia, uta, Baurú ulcer, etc.

HISTORY OF THE DISCOVERY OF THE PARASITES OF LEISHMANIASIS

Leishmanias were first recognized by Leishman (1903). *In the* same year, Donovan described these parasites in a disease called "dum dum fever" or "kala azar." Laveran and Mesnil examined some of Donovan's specimens and proposed the name *Piroplasma donovani*. Ross (1903), however, concluded that this organism was not a sporozoan and created for it the genus *Leishmania*. Nicolle (1908) gave the name *Leishmania infantum* to the parasite which causes kala azar in the Mediterranean area. Wright, in 1903, described a similar organism in a case of Oriental sore in a child from Syria, who had been taken to Boston. He proposed the name *Helcosoma tropicum* for this parasite. Later it was included in the genus *Leishmania*. *The correct name of the parasite which causes Oriental sore is Leishmania tropica* (Wright, 1903). *L. donovani* is identical with *L. infantum*.

American Leishmaniasis

1. **Cutaneous Form.**—The Indian ceramists of the pre-Columbian age in Peru represented on their vases or *huacos* numerous pathologic changes which medical observers and historians later recognized as certain diseases. Tamayo (1909) was the first to recognize *the lesions shown on the* Peruvian huacos as a condition long known as "uta", that is, mucocutaneous leishmaniasis.

In 1895, Greda, in Italy, described the disease in Italians who had returned to their country from São Paulo. In 1908, numerous patients from certain regions *began to report* to the Santa Casa de São Paulo Hospital with a disease at that time known by several names, Baurú ulcer, wild wound, northwest ulcer, etc., but the etiology was not yet known.

tion, and chiefly by agglutination tests, Marques da Cunha and F Chagas (1937) separated the leishmania which causes *American visceral leishmaniasis* from *L donovani* and *L. infantum* and called it *L. chagasi* Marques da Cunha, however, after further studies, concluded that agglutination is not an adequate *method for separating the various species of the* genus Leishmania For that reason, *L chagasi* has become synonymous with *L donovani*.

MUCOCUTANEOUS LEISHMANIASIS

GEOGRAPHICAL DISTRIBUTION

The presence of mucocutaneous leishmaniasis has been noted throughout most of Latin America from Mexico to the northern part of Argentina The disease shows high incidence *in certain regions*, particularly in parts of Peru and Brazil

In Brazil, the disease is most frequent in São Paulo Silveira (1919) estimated that *there were 15,000 cases in São Paulo*, Pessôa (1941), over 40,000 patients in the endemic region

ETIOLOGIC AGENT

The etiologic agent of mucocutaneous leishmaniasis is *L braziliensis* It has two forms one, the nonflagellate, leishmania form, which is found in the human tissues and in animals susceptible to inoculation with the parasite, the other, the flagellate, leptomonas form *which is found in the digestive tube* of the vector host and in cultures

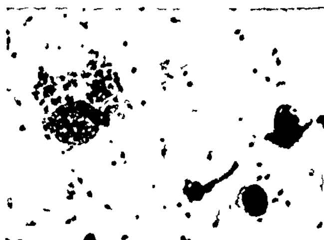

Fig 73 —Smear of material obtained from puncture of a nonulcerative lesion A macrophage containing 62 leishmanias may be observed (Giemsa stain) (After Pessôa and Barretto in I Meeting of Derm Syphil Brazil 1944)

The nonflagellate type might be found also in the invertebrate host just as the flagellate *type might be seen, very rarely, of course,* in the vertebrate host

1 **Forms Observed in the Vertebrate Host**—The leishmania forms appear very often within the cells of the reticuloendothelial system, in smears they generally appear outside the cells due to rupture of the cells while preparing the slides

The typical leishmanias are oval, with one extremity more rounded than the other They measure from 2 to 4 microns by 1 5 or 2 5 microns This form is susceptible to variations The distinguishing *features of the parasite* are the cytoplasm, the nucleus and the kinetoplast

2 **Forms Observed in the Insect Vector.**—When the leishmania forms are ingested by the insect vector, they evolve more or less rapidly to produce the flagellate form

On March 30, 1909, Lindenberg reported discovery of the parasite of Bauru ulcer, this parasite being identical with the agent of Oriental sore This discovery was later confirmed by Carini and Paranhos In 1911, Pedroso and da Silva using N N N medium succeeded in cultivating the leishmania from Bauru ulcer In the same year Splendore demonstrated leishmanias in the lesions of the mucosa In Peru Escomel (1911) found the parasite and identified espundia a disease characterized by slow and progressive ulceration of the bucopharyngeal mucosa, as leishmaniasis

In 1911, Gaspar Vianna considered the differences between the etiologic agents of mucocutaneous leishmaniasis and *L tropica* and proposed the name *Leishmania braziliensis*

Fig ? Peruvian huaco showing lesions attributed to American skin leishmaniasis (After Nelva and Barbará, 1917 First Conference South Amer Soc. Microb & Parasit) Buenos Aires)

2 **Visceral Form.**—The first reference to the possible existence of visceral leishmaniasis in South America was made by Carlos Chagas who while traveling in the valley of the Amazon in 1911 1912 suspected the existence of kala azar in that region Migone (1913), in Paraguay was the first to observe a fatal case of kala azar in the capital of that country Mazza and Arias (1926a) later reported two cases of infantile kala azar in northern Argentina In 1934 Penna reported this infection in 41 sections of liver out of 47 000 specimens Research by a Commission of the Oswaldo Cruz Institute showed the frequency of leishmaniasis in Brazilian territory and clarified the principal points in the etiology, pathogenicity and epidemiology of the disease With the aid of animal inocula

Aragão (1922) found leptomonas in the digestive tube of *Phlebotomus intermedius* and reproduced the ulcer in dogs Pifano (1940), in Venezuela found *Phlebotomus sp* naturally infected by leptomonas in regions of mucocutaneous leishmaniasis

1 In the state of São Paulo there is a notably definite relationship between distribution of the disease and of the *Phlebotomus whitmani*, *Phlebotomus pessoai*, and *Phlebotomus migonei* In regions of endemicity, these three species constitute almost the entire Phlebotomus fauna (Barretto 1943)

There is a two month lapse or period between the maximum incidence of Phlebotomus and new cases of leishmaniasis, this period of two months being within the accepted limits of the incubation period of the disease

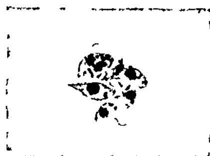

Fig 76—Leptomonas stages in a culture of *Leishmania braziliensis* in NNN medium (Original)

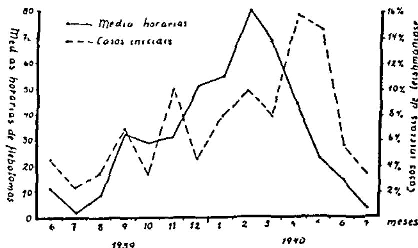

Fig 77—Graph showing the relationship between monthly incidence of Phlebotomus caught with human bait in Pompéia and incidence of early cases of mucocutaneous leishmaniasis (After M P Barretto 1943 In *Observações sôbre a biologia em condições naturais dos flebótomos do Estado de São Paulo* Thesis)

2 Pessôa and Pestana (1940) also found *P migonei* infected Coutinho (1940) observed *leptomonas forms in P pessoai* Finally, Pessôa and Coutinho (1941), examining by dissection and microscopically a total of 9 273 specimens of Phlebotomus found 0 22 per cent to be naturally infected

3 After feeding on individuals or animals infected with *L braziliensis*, the Phlebotomus becomes infected Pessôa and Coutinho (1941) fed *P whitmani*

Culture

Rogers (1904) was the first to cultivate a parasite of the genus Leishmania Nicolle, while studying visceral leishmaniasis in Tunis, showed that *L donovani (L infantum)* can be easily cultivated in the water of condensation of rabbit blood agar, devised by McNeal and Novy for cultivation of *Trypanosoma lewisi* A modified medium has come to be known as N N N medium In 1908, Nicolle successfully cultivated *L tropica* Lindenberg in 1909 and Pedroso and da Silva in 1911 obtained the same results with *L braziliensis*

Fig 74 —*Leishmania braziliensis* Parasites in rosette pattern Smear from an ulcer (Original)

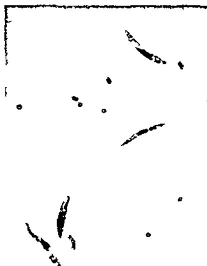

Fig 75 —*Leishmania braziliensis* leptomonas stages found in the pharynx of *Phlebotomus whitmani* naturally infected (Original)

TRANSMISSION

Transmission by Phlebotomus

Long ago the intimate relationship between incidence of Phlebotomus and mucocutaneous leishmaniasis was noticed Several authors, such as Neiva and Penna (1916), Neiva and Barbará (1917) Pirajá de Silva (1918), and Cerqueira (1919), studied the possibility of the transmission of the protozoan by the Phlebotomus

EPIDEMIOLOGY

Latitude—Skin leishmaniasis has been found as far north as 21 degrees in the peninsula of Yucatan and as far south as 30 degrees in Argentina (Bernasconi 1928) as well as in Brazil (Pinto 1942)

Altitude—Altitude is a factor which limits the distribution of the disease for in leishmaniasis as in malaria the vectors become scarcer as the altitude becomes higher Nevertheless Escomel (1929) reported the disease in Peru at an altitude of 2 500 meters above sea level According to Weiss (1943) ' uta (exclusively cutaneous type) has been found in the high regions of the Peruvian Andes at an altitude of 1 200 to 2 800 meters above sea level The dangerous mucocutaneous type espundia is found in the low regions in the forests

Climate—In regions with low temperatures the disease is found along water courses and in the low areas In high temperature areas it is found in the high places where the temperature is suitable to the development of the vector and also of the leishmania in the body of the Phlebotomus

Season—In Sao Paulo Brazil according to Pessôa (1941) the largest numbers of cases appear in autumn (April and June) and they are less numerous in winter and early spring (July and October) Cases occur however throughout the entire year due to the occasional extremely long periods of incubation In Mexico Beltran and Bustamante (1942) noted a high incidence of leishmaniasis from September to December which corresponds to autumn in that part of America

Geography Affected—As opposed to kala azar and Oriental sore American cutaneous leishmaniasis has been shown from the first epidemiologic studies to be a typically sylvan disease

Pessoa (1941) showed that this fact is related to the biology of the transmitting Phlebotomus exclusively sylvan in habits which is found in the woods in great numbers at the time when the weather is hot and after summer rains Since the vector insects do not develop within dwellings or in their immediate vicinity the disease is not found in urban zones even in those cities and villages which are situated in highly endemic regions

Age Sex, and Race—Leishmaniasis attacks without reference to age sex or race Influence of age and sex is connected with the possibility of more or less exposure to the disease The yellow races (Japanese) are not as frequently infected as the white and colored races because as a rule they do not work in the woods Brazilians clear out the forests after which the Japanese settle in districts that have been cleared On certain farms where white black and yellow children live under identical conditions no significant difference has been observed in the incidence of the disease

PATHOGENESIS

General Remarks

The invasion of the human body by *Leishmania braziliensis* usually occurs in the unprotected skin by direct inoculation of the parasite in leptomonas form through the bite of the Phlebotomus After a period of incubation

and obtained 2 17 per cent infections In like manner *P fischeri* were fed, and 0 41 per cent infections obtained

The species which seem to play a predominant role in the dissemination of the disease in São Paulo are the *P whitmani*, *P pessoai*, and *P migonei* The *P fischeri*, with its high incidence in regions of sporadic cases of leishmaniasis, with the possibility of its being experimentally infected, and its marked anthropophilia, seems to be the transmitter of the disease in certain regions

Other Processes of Transmission

1 **Direct Contact**—The possibility of transmission by direct contact has been accepted by several authors

2 **Nonhematophagous Arthropods**—Nonhematophagous arthropods have been incriminated as transmitters of the disease At the present time however, this idea is not accepted because American leishmaniasis is a disease acquired in the forests where flies are not so abundant as in the cities The disease is endemic only in certain definite regions whereas the housefly and other flies can be found everywhere

TABLE X

CLINICAL ASPECTS OF AMERICAN CUTANEOUS LEISHMANIASIS

I Cutaneous	Nonulcerative	(a) Papular (initial)		
		(b) Impetiginous		
		(c) Tuberiform	Sparse	
			In groups	
			In patches	
			Diffuse infiltrative (lupoid) etc	
		(d) Nodular hypodermic		
		(e) Fungoid	Frambesioid	
			Verruciform	
	Ulcerative	(a) Ecthymatiform		
		(b) Ulcerous		
		(c) Fungoid ulcer		
		(d) Nodular ulcer		
II Mucocutaneous	1 With mucous lesion and without apparent cutaneous lesion			
	2 With mucocutaneous lesion	Cutaneous lesion (item I)		
		Mucous lesion	(a) Infiltrative (initial)	
			(b) Ulcerous	
			(c) Fungoid ulcer	
			(d) Fungoid	
III Lymphathic	(a) Adenitis (initial)			
	(b) Adenolymphangitis			

3 **Hematophagous Arthropods, Exclusive of the Phlebotomus**—Several authors have cited hematophagous arthropods other than the phlebotomus as transmitters Da Matta (1910) Flu (1911) Lindsay (1914) etc incriminated ticks, Brumpt and Pedroso (1913), the Tabanidae (horseflies) Phlebotomus however, is probably the only hematophagous arthropod which plays an important role in the transmission of American leishmaniasis

transformed into a large ulcer with infiltration of the margins and slow increase in size indicating that a particular infection has attacked the wound and may determine its later development

CLINICAL ASPECTS

The following classification of the clinical aspects of this disease is taken from the schema of Rabelho (1925) (slightly modified)

Ulcerative Forms—These are the most common They include types indicated in the general picture The ulcerative lesions of cutaneous leishmaniasis show loss of deep substance varying in size frequently attaining or even exceeding 10 cm in diameter These lesions with clear projecting borders have at times high margins intensely infiltrated at times they are irregular moist and violaceous

Fig 78—Mucocutaneous leishmaniasis Ecthymatiform lesion (Original of Aguiar Pupo)

The exudate is serous at times with a purulent secretion stagnating under the brown membrane with which the base is covered and which lies at the level of the surrounding skin If the membrane is detached one can see a bright red base with gross granulations which bleeds easily The infiltrated margins vary greatly in width and height In recent cases the edges are sharp while in older cases the ulcerated surface is gradually lost Often around the larger ulcers smaller ulcers form papular in appearance at first later becoming superficial ulcers

Nonulcerative Forms—The most common nonulcerative forms are the impetiginous and the tuberiform the latter being grouped or scattered They may also be verrucose or frambesioid The last are most commonly encountered The verrucose lesions have a clearer outline and are round with surfaces of irregular wart like form markedly irregular with exudation in the early stages and hard scabs in old dry stages The frambesioid variety is

during which the parasites multiply actively in the form of leishmanias in the histiocytic elements of the skin there appears the initial lesions This is a papule or papular erythema The parasitic corpuscles are found in this lesion

These primary lesions may regress and present an abortive course they may remain stationary, or there may slowly develop skin nodules or in some cases they may further progress to the formation of ulcerative lesions accompanied by neighboring glandular tumefaction These ulcers are at times of a torpid character, at times they go on to natural cicatrization In other cases the lesions progress and at times present a vegetative character with no tendency to spontaneous cure Then by a mechanism as yet not clearly defined by metastasis of the primary lesion the parasites invade the nasobucco pharyngeal mucosa and cause ulcerative or vegetative lesions of a chronic course only rarely with a tendency to spontaneous cure The disease is chronic with a general tendency to invade the mucosae The possibility of a spontaneous cure varies greatly according to geographical areas to the type of lesion and to the part of the skin affected

The disease is also characterized by its irregular course there being no chronology as to the appearance of the various localizations or pathologic manifestations

Period of Incubation

The minimum period of incubation for leishmaniasis of the skin is unknown but according to our observations it is generally short ten to twenty five days Longer periods of incubation have been observed in patients and in experimental animals in some cases as long as ten months to a year

Initial Lesions

After the period of incubation the initial lesions appear These are in the form of papules without any definite identifying characteristics These papules which may or may not be pruritic are accompanied by sensation of heat or pain

The initial stages less frequently assume other characteristics such as erythematous papular lesions of the skin impetiginous lesions small skin nodules etc In the beginning of the disease there is often neighboring lymphadenopathy without apparent involvement of the lymphatic vessels the initial leishmanial lesion is a veritable cutaneous glandular complex Parasitologic examination of the initial lesion shows a great quantity of parasitic corpuscles which are also found in the enlarged lymph nodes The ulcerative process in the initial papule by virtue of necrosis of the outer derma proceeds to the epithelium Detachment occurs with release and scattering of the necrotic material creating an ulcer called "espundia cancrum by Escomel (1911) and espundia cancerum initial cancrum" or cancrum of inoculation by Argentine authors

Another form of beginning ulceration mentioned by several authors is traumatic These cases generally refer to patients with a traumatic lesion which cicatrizes at first only to open later or which may slowly become

In Mexico according to Beltrán and Bustamante (1942), and in Costa Rica according to Rotter and Peña Chavarría (1935) there is a predilection for the ears then the arms the number of ulcers found on the legs and feet being very small Our own experiences have verified the localization in the ears in a percentage of 0 8 to 5 3

Fig 80

Fig 81

Fig 80 —Mucocutaneous leishmaniasis. Ulcerative lesions with fungoid aspect. (Original)
Fig 81 —Mucocutaneous leishmaniasis Papulotuberiform lesions. (Original of Aguiar Pupo)

Mucosal Form—One of the most typical characteristics of American leishmaniasis is the frequency with which the parasites produce lesions in the nasobucco pharyngolaryngeal mucosa This is the difference between cutaneous leishmaniasis and Oriental sore where lesions of the mucosa are exceptional The invasion of the mucosa in American leishmaniasis is a secondary manifestation of the cutaneous lesion Quite often it is difficult to demonstrate lesions in the skin since the disease may have an abortive course without leaving a scar In about 10 per cent of the cases the cutaneous lesions appear simultaneously with lesions of the mucosa but the mechanism should not be considered the same as that in syphilis Although some authors believe

characterized by soft papillomatous lesions resembling those of yaws or bouba This type is called figueira ' in the Amazon (Chagas 1913) and can appear clinically like pé musgoso of pe verrucoso which are caused by various agents *constituting a syndrome This syndrome is found relatively* frequently among our people especially in hospitalized leishmaniasis patients

Lymphatic Form —Lymphangitis and adenitis occur frequently in leishmaniasis The lymphatic vessels are transformed into thick cords of uniform diameter not painful at times with dilatations easily palpable through the skin Such nodules may rupture and become new ulcers This lymphatic form is quite similar to leishmanial lymphangitis and sporotrichosis The lymphatic glands are frequently involved in the initial lesions as well as in the later stages of the disease Marked enlargement of the glands is not very common they are seldom larger than a hazelnut

Fig 79 —Mucocutaneous leishmaniasis Ulcerative lesions (Original)

Number and Localization of the Lesions

There are usually very few lesions one to three there are however some *cases in which* one may find more of these lesions scattered over the body

The lesions are usually found on the exposed parts of the body

In Mexico according to Beltran and Bustamante (1942) and in Costa Rica according to Rotter and Peña Chavarria (193?) there is a predilection for the ears then the arms the number of ulcers found on the legs and feet being very small Our own experiences have verified the localization in the ears in a percentage of 0 8 to 5 3

Fig 80

Fig 80 —Mucocutaneous leishmaniasis Ulcerative lesions with fungoid aspect. (Original)
Fig 81 Mucocutaneous leishmaniasis Papulotuberiform lesions (Original of Aguiar Pupo)

Mucosal Form —One of the most typical characteristics of American leishmaniasis is the frequency with which the parasites produce lesions in the nasobucco pharyngolaryngeal mucosa This is the difference between cutaneous leishmaniasis and Oriental sore where lesions of the mucosa are exceptional The invasion of the mucosa in American leishmaniasis is a secondary manifestation of the cutaneous lesion Quite often it is difficult to demonstrate lesions in the skin since the disease may have an abortive course without leaving a scar In about 10 per cent of the cases the cutaneous lesions appear simultaneously with lesions of the mucosa but the mechanism should not be considered the same as that in syphilis Although some authors believe

Fig 82 —Mucocutaneous leishmaniasis Verrucose papillomatous lesion (Original of Aguiar Pupo)

Fig 83 —Mucocutaneous leishmaniasis Ulcerative lesions and nodules developed in the lymphatic course (Original of Aguiar Pupo)

that infection of the mucosa is due to autoinoculation the majority feel that it is disseminated through the blood stream or lymphatics Villela Pestana and Pessoa (1939) showed that in certain cases localization of the parasites in the mucosa occurs very early Material from currettage of the nasal mucosa in cases with primary skin lesions has revealed parasites in spite of its normal appearance

Initial ulcerations of the mucosa *locate almost always in the nasal* mucosa they begin with hyperemia of the anterior part of the cartilaginous process

Fig 84 —Mucocutaneous leishmaniasis mutilating type Fungoid ulcer of the right forearm and hand destructive lesions of both ears nasal lesion with destruction of the soft parts of the nose and involvement of the upper lip (Original)

After the ulcer has formed it extends deeply into the tissue until there is destruction of the mucosa and invasion of the septal cartilage and of the contralateral mucosa which becomes infiltrated and ulcerated Perforation of the nasal septum is one of the most common consequences of nasal leishmaniasis In many cases the external appearance of the nose remains normal for a relatively long period of time although internally a great deal of damage has been done Destruction is not limited to the membrane of the

Fig 82.—Mucocutaneous leishmaniasis Verrucose papillomatous lesion (Original of Aguiar Pupo)

Fig 83.—Mucocutaneous leishmaniasis Ulcerative lesions and nodules developed in the lymphatic course. (Original of Aguiar Pupo)

septum and to the quadrangular cartilage but may advance and destroy the entire *cartilaginous* frame of the nose, thus causing horrible disfiguration of the patient's face. The ulceration may extend still further and involve both the upper and lower lips, causing dreadful mutilation Generally the bony frame of the nose is preserved

Nasal lesions are persistent, progressive, resistant to therapy, diffuse, by *contiguity* they invade the rhinopharynx, principally the soft palate, the tonsils and their pillars, the posterolateral walls of the pharynx, the larynx, the trachea, and even the tongue and gums In the pharynx, the infiltrative, proliferative process may cause fusion of the uvula, the pillars, the lateral cords, and the posterior wall

Finally, in rare cases, leishmaniasis may localize in the genital or ocular mucosae

Fig 87—Cutaneous lesion in skin leishmaniasis Note marked acanthosis (Original)

Frequency of Localization in the Mucosa: The frequency with which leishmaniasis localizes in the mucosa varies considerably While almost non-existent in certain regions, as in Mexico (peninsula of Yucatan), in other regions, as among us here in Brazil, it is very common

PATHOLOGY

Skin leishmaniasis, from the histopathologic point of view, is a granuloma composed of lymphocytes, plasmocytes, and histiocytic elements, at times in equal numbers, at times with one or another of these types of cells predominating, infiltrating the derma One may notice, in the epithelium, a prolifera-

Fig 85—Mucocutaneous leishmaniasis mutilating type Destruction of soft parts of the nose and involvement of pharynx mouth lips etc (Original)

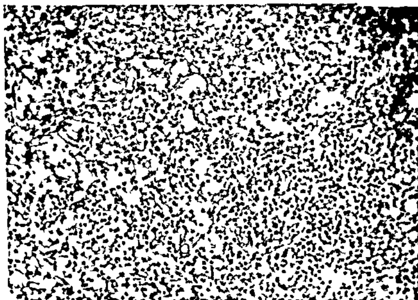

Fig 86—Section of a cutaneous lesion in American skin leishmaniasis. The skin is infiltrated There are seen multiple connective tissue cells and intense lymphocytic infiltration with some plasmocytes and histiocytes. (Original)

by Klotz and Lindenberg (1923) They pointed out the formation of circumscribed nodules of histiocytic cells which characterize the stage of ulceration

There are many leishmanias in the initial papular lesion or dermic nodule —they may be found in extraordinary numbers Leishmanias are also numerous in the margins of recent ulcers which tend to progress rapidly, they usually decrease or even are absent in old and chronic ulcers with a torpid course *As to parasitism cutaneous and mucosal lesions behave in the same way*

Fig 89 —Mucocutaneous leishmaniasis Section of an early lesion of the skin to show the intense parasitism (Original)

NATURAL AND EXPERIMENTAL INFECTION IN ANIMALS

Natural Infection

Pedroso (1923 and 1923a) observed a total of four cases of spontaneous leishmaniasis in the dog Mazza (1926), in Argentina found several dogs with ulcerations in the ears and in the flanks and discovered leishmanias in two In 1927 Mazza reported finding leishmanias in ulcers of a dog and in an ulcer

tive phenomenon—acanthosis. Usually necrosis is produced in the center of the granuloma with loosening of the epithelium and formation of the ulcer. Less frequently the lesion does not ulcerate, constituting the nonulcerative type.

The ulcerative lesions consist of waste substances varying in extent but they extend no deeper than the middle of the derma. *In the smaller lesions* alterations in the margins cause little change in contour of the ulcer. In larger ulcers the epithelial changes are more pronounced and there may be observed marked acanthosis invading the derma in the form of thin epithelial cords close together. Giant cells are sporadic. Well defined tuberculoid structures absent in rapidly progressing recent ulcers can be found in the chronic ulcers

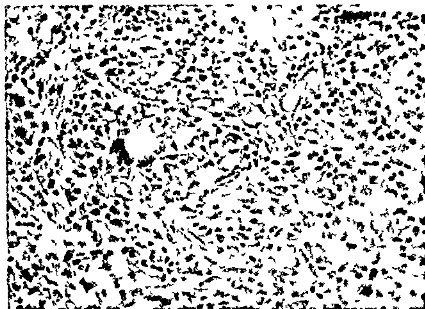

Fig. 66.—Section of mucocutaneous leishmaniasis showing an accumulation of histiocytes and a giant cell. (Original.)

where also well defined tuberculoid nodules can be seen. Eosinophiles are generally not abundant; neutrophiles are found in greater numbers in the vicinity of the ulcer. Fibroblasts, absent in recent ulcers, are found in increasing numbers in the older ulcers with a tendency toward cicatrization.

There is no difference from the histopathologic point of view between the verrucose and papillomatous types. There is always thickening of the skin layers. The stratum spinosum also becomes thickened and there is a formation of horny masses which accumulate in the interpapillary spaces. This proliferation may extend irregularly into the subjacent tissues. The changes involve the derma, intensely infiltrated by histiocytic elements, with elongated and proliferous papillae. Lesions of the mucosae have been thoroughly studied

It is also necessary to differentiate this disease from sporotrichotic lymphangitis this is clinically impossible and is exclusively a laboratory procedure It is also necessary to differentiate it from ecthyma and impetigo In the differential diagnosis between nasal syphilis and leishmaniasis it should be remembered that leishmaniasis affects the cartilaginous parts while syphilis affects the bony structure of the nose Finally leishmaniasis might be confused with Toula and blastomycosis and more rarely with cutaneous and mucosal tuberculosis or with leprosy In all these cases the finding of the etiologic agent solves the problem

LABORATORY DIAGNOSIS

Demonstration of the Parasite

The most important laboratory test is the demonstration of the parasite by direct methods—finding it in the ulcers glands or by culture

Parasites can be demonstrated in material taken from lesions of the skin and the mucosa as well as from glands For this purpose curettage puncture or biopsy may be used As soon as the material is obtained it must be placed in culture media or sectioned for microscopic examination In closed lesions puncture with a large needle is advisable

To find the parasite in the nasal mucosa curettage must be performed after anesthesia with Neotutocaine Material obtained should then be smeared on slides and stained by the Giemsa method

Culture in appropriate media according to some authors increases the possibility of finding the parasite It must be remembered that leishmanias do *not grow in the presence of other microorganisms so that several tubes must* be used to make the culture

Serologic Reactions*

Serologic reactions used for the diagnosis of kala azar do not give satisfactory *results in cutaneous leishmaniasis Complement fixation tests are very* complicated and not very successful because of lack of a good antigen

Intradermal Reaction*

The intradermal reaction also called Montenegro s test is an allergic *reaction It was introduced by Montenegro (1926) and is based on the* work of Wagner (1923) The test was later thoroughly studied by Buss (1929) Gomes (1939) and Pessoa and Pestana (1940)

The antigen is a suspension of leptomonas in phenolized saline solution It is injected intradermally in dosage of 0 1 to 0 2 c c Positive reactions show *the formation of a specific papule* which attains maximum development in forty eight hours remains four or five days and then regresses and disappears in about four days more or less according to its intensity This test gives a high percentage of positive results (about 95 per cent) *It may be negative* in early cases but in such cases parasites can always be found

*See also Chapter 72

in the eye of a horse Mello (1940) at Belém, Pará (Brazil), found numerous leishmanias in material from ulcers in the ear and nose of a cat

Such findings seem to be merely accidental, since examinations have been made of hundreds of cats and dogs, as well as wild animals, without observing any lesions of leishmaniasis Thus dissemination of skin leishmaniasis cannot be attributed to animals

Experimental Infection

The disease has been produced experimentally by inoculation of triturated tissues containing the parasites or by the use of cultures of leishmania in dogs monkeys, and mice [Editor's Note (O F) Hamsters are being used in many laboratories]

More recently, Fuller and Geiman (1942) reported that they had found an animal very susceptible to inoculation with *L braziliensis*—the Texas squirrel, *Citellus tridecemlineatus*

CLINICAL DIAGNOSIS

Cutaneous Form

In general, a diagnosis of cutaneous leishmaniasis is not difficult if the lesions assume the aspect of a typical ulcer Often a glance at the lesion is sufficient to establish its nature If, however, the lesions are verrucose, frambesioid, lymphangitic, etc , they might easily be mistaken for other disease entities, and it is very difficult to make a correct diagnosis In such cases one must make use of laboratory tests The anamnesis aids in clarifying the diagnosis

Mucosal Form

In this type, the anamnesis is very important, because the patients speak of previous lesions of the skin and some of them still carry the evolutionary cutaneous ulcer When these ulcers are no longer present one may find the scars As stated above, in some cases the patients show no skin lesions or subsequent scars The site of the lesion, in the cartilaginous portion of the septum, its granulations and general appearance, all help to make the diagnosis Local edema and hypertrophy, principally of the upper lip, give the patient's face a characteristic appearance which some authors call "facies leishmaniotica " and others "tapir face "

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other tropical diseases which are predominant in endemic zones One of the most common of these is tropical ulcer Tropical ulcer localizes in the lower third of the leg, exceptionally in other parts of the body The pain tendency to bleed, abundant suppuration, and odor all are elements which help in the differentiation of the two ulcerative processes

upon lesions of the mucosa to be superior to that of tartar emetic. In this author's experience, however, Fuadin has proved inferior to tartar emetic *for lesions of the mucosa and not superior for lesions of the skin.* One great advantage of Fuadin over tartar emetic is that it can be used by the intramuscular route.

Eparseno (Amino Arseno Phenol)

Eparseno was introduced in the treatment of leishmaniasis by Pupo (1926). It is a glucoside of arsphenamine dioxy diamido arsenobenzol (Manson-Bahr). Each 1 c.c. of Eparseno contains 0.12 Gm. of amino arseno phenol. It is given by injection at two-day intervals. For children there is a proprietary called Infantile Eparseno, *each cubic centimeter of which contains 0.05 Gm. of* the salt, this dosage being used for each 10 kilograms of body weight by intramuscular or intravenous injection.

In general, a series of 10 ampules is given, followed by an interval of ten days, until 40 or 50 ampules, according to the patient's tolerance, have been used. Due to the arsenic content of this drug, toxic phenomena occur at times, such as *diarrhea, intestinal colic, erythrodermia and polyneuritis. In such* cases, treatment should be immediately discontinued and preparations containing vitamin B, as well as strychnine injections, should be used. Injections of Eparseno are the most efficacious means of treating this disease. Lesions of the mucosa refractory to antimony are more rapidly cured with Eparseno. Eparseno is also efficacious in the treatment of cutaneous forms of the disease, cicatrizing the ulcers in a relatively shorter time than tartar emetic. Nevertheless, relapses occur quite often, about as often with Eparseno as with tartar emetic.

Sodium Arsenite

This arsenical compound also was introduced in the treatment of *cutaneous leishmaniasis by Pupo (1935). It is used in doses of 2 to 5 mg. by* intramuscular injection.

It acts efficiently in leishmanial ulcers of the skin. However, relapses are *more common with this treatment than with tartar emetic, and its action on* the mucosa is noticeably inferior to that of Eparseno or tartar emetic.

LOCAL TREATMENT

For the local treatment of lesions, disinfectant substances such as lactic acid are used, or injections of Atabrine, emetine or phosphorated oil are made into the base of the ulcer. Thermocautery and diathermic *fulguration* and coagulation have also been used with more or less success.

Such local treatment is merely adjuvant and should always be used with specific general treatment in the form of injections of antimony or arsenicals.

PROPHYLAXIS

Campaign Against Vector.—We have found that it is virtually impossible to destroy the larval foci of Phlebotomus since we do not know the natural breeding places of the transmitting species.

THERAPY

Tartar Emetic

Tartar emetic was used for the first time in the treatment of cutaneous leishmaniasis by Gaspar Vianna in 1912 It must be used by intravenous injection in a 1 or 2 per cent solution Dosage for adults is 0 10 Gm three times a week the initial dose being 0 06 Gm In children from 6 to 12 years of age a dose of 0 05 Gm is used Injections must be given every other day in a series of twelve to fifteen injections, with an interval of ten to fifteen days Three or four series of treatments are given according to the case and the tolerance of the patient

This drug is not always well tolerated There may be immediate or delayed reactions The immediate bad effects are cough brachial neuralgia nausea and vomiting Delayed reactions are headache various eruptions albuminuria etc These symptoms appear principally after the use of doses larger than 0 10 Gm A very common phenomenon which constitutes one of the greatest inconveniences connected with the use of tartar emetic is rheumatic pain The injections also cause painful reactions in the veins of the arm because this drug causes a certain degree of phlebitis

The treatment must be prolonged even after the period of cicatrization until there is complete disappearance of the nodules or thickenings of the skin Otherwise the lesions reappear within a short time and the therapy already given is useless In the papillomatous and verrucose types which are the more resistant to treatment recurrences are more frequent Recent cutaneous lesions are more prompt to show the beneficial effects of the medication The effect of tartar emetic upon mucosal lesions is the same as upon the skin Recurrences however of lesions of the mucosa are more common

Fuadin (Neoantimosan)

Fuadin was introduced for the treatment of cutaneous leishmaniasis by Mazza and Arias (1931) in Argentina where it is prepared by Bayer and sold commercially in solutions of 6 3 per cent concentration in 1 5 c c and 5 c c ampules The complete series is 30 c c or approximately 1 9 Gm of Fuadin equivalent to 0 30 Gm of antimony

Fuadin is given intramuscularly every other day For adults the first injection should be 1 c c the second 1 5 c c and the third 3 5 c c Following this the 3 5 c c dosage is repeated on alternate days or 5 c c are given every three days Two or three series of eight to ten injections are given with intervals of two or three weeks between the series Dosage for women is two thirds of the dosage for men for children it is 1 c c per each 10 kilograms of weight

Reactions to the use of Fuadin are cough nausea fever, etc In treatment with Fuadin the efficacy of which has been stressed by many authorities, relapses are also common and treatment must be given long after apparent cure of the lesions Mazza and collaborators considered the action of Fuadin

TRANSMISSION

Although *L tropica* can be transmitted by direct contact a fact known for a long time and through the mechanical vehicle of the bite of hematophages among them the *Stomoxys calcitrans*, as shown by Berberian (1938), today it is believed that transmission in nature is effected chiefly through the bite of the Phlebotomus

Adler and Ber (1941) succeeded in demonstrating the transmission of *L tropica* to man (five times out of nine attempts) through the bite of *P papatasii* Other vectors are *P sergenti* and *P caucasicus*

IMMUNITY

According to Thomson (1931) it is believed in Mesopotamia that Oriental sore establishes active immunity and it is customary in routine practice deliberately to inoculate the children in the covered parts of the body to prevent later disfiguration of the face by the naturally acquired disease Nicolle and Noury Bey also state that experimental ulcers confer immunity According to Marzinowski (1928) such immunity has been considered possible for many years Colvilli cited by this author reports that the Jews of Bagdad in order to keep their children from acquiring the disease used to inoculate these children beneath the skin with the serous substance from ulcers

Marzinowski (1928) inoculated himself as well as several of his assistants with exudate from an ulcer All those inoculated showed immunity to new inoculations for seven years following the first inoculation

Adler cited by Thomson (1931) stated that after natural cure of an experimental leishmanial ulcer no new infection followed although the same strain and another biologically different strain were used In the East Marzinowski (1928) Berberian (1939), Gitelson (1928) Lawrow and Dubowskoj (1937) and others have been using as the preferred method of immunization inoculations with living cultures They inoculate with living cultures of *L tropica* which after a period of incubation varying from two to six months cause ulceration which develops into a benign form healing in six to twelve months The last two authors have made more than 500 vaccinations with living cultures They state that no complications have been observed In all cases real immunity is established

PATHOGENICITY

In man the disease is limited to cutaneous tissue and should be designated "cutaneous leishmaniasis" The period of incubation varies from several days to several months The lesion is initiated by a papule which is transformed into an ulcer In cases uncomplicated by bacteria or other microorganisms the lesions show a tendency toward cicatrization and heal at the end of six months or a year leaving a permanent scar Various forms of the disease have been described

Attacks against the adult forms offer more hope of success. Good results are expected from the use of DDT, its action having been proved against several species of arthropods.

Defense Against the Bite of the Phlebotomus.—First there is a need to construct dwellings at a distance from the jungle. According to Takaoka (1928) Phlebotomi do not fly far, so that location of homes more than 100 meters from the woods will prevent invasion by these diptera. Protection of dwellings by netting is not possible in our endemic zones.

Finally, we can recommend the use of mosquito netting, of repellents and the protection of the exposed parts of the body by leggings, gloves, etc. Such methods, while theoretically interesting, are very difficult to apply practically.

Preventive Vaccination.—Preventive vaccination was used by Pessoa and Pestana (1940) and their collaborators of the Commission for the Study of Leishmaniasis. One preventive vaccine is composed of a phenolized suspension of leptomonas, each cubic centimeter of suspension contains 100 to 120 million of these organisms. Three injections with one week interval are made. There is little reaction and the vaccine is well tolerated. Pessoa (1941) demonstrated the efficacy of this vaccination in a highly endemic zone (Table XI).

TABLE XI

RESULTS OF PREVENTIVE VACCINATION AGAINST MUCOCUTANEOUS LEISHMANIASIS (After Pessoa, 1941)

	NUMBER	NUMBER OF PATIENTS WHO DEVELOPED LEISHMANIASIS	PERCENTAGE
Vaccinated	444	12	[illegible]
Not vaccinated	693	108	15.6

CUTANEOUS LEISHMANIASIS

GEOGRAPHICAL DISTRIBUTION

Cutaneous leishmaniasis is endemic in several countries of the Mediterranean area: Italy, Greece, Spain, Morocco, Algeria, Tunis, Tripoli and Egypt. It also is found in some regions of Africa: Abyssinia, Nigeria, French Congo, etc. It is very common in Syria, Palestine, Saudi Arabia, Iraq and other countries of Asia Minor as well as in certain regions of the U.S.S.R. as in the Caucasus and Southern Russia. There are many cases in India and Indochina.

ETIOLOGIC AGENT

The etiologic agent of cutaneous leishmaniasis or Oriental sore is the *Leishmania tropica* (Wright, 1903), the morphology of which is identical with that of *L. braziliensis*.

CULTIVATION

L. tropica was cultivated for the first time by Nicolle in N.N.N. medium. Forms and development are identical with those of *L. braziliensis*, previously described.

Cultivation

Cultures of L donovani may be obtained from the spleen, as Rogers (1904) first demonstrated or from some other organ in which the parasites exist Mayer and Werner (1914) and Wenyon (1914) cultivated them from blood *Shortt and others (1923) succeeded in cultivating them from centrifuged urine*

The behavior and morphology of this species in cultures are the same as those of *L braziliensis*

Fig 91—Section of liver in visceral leishmaniasis Observe the intense parasitism in the endothelial cells (Original)

Habitat

L donovani is found in man in the endothelial cells of the capillaries of the viscera especially of the spleen liver the bone marrow the intestinal mucosa and the mesenteric glands *Leishmanias may* also be found in endothelial cells of the kidney suprarenal capsule lung and the meninges

PATHOGENESIS

The disease is a reticuloendotheliosis due to invasion of the reticular tissues by leishmanias The blocking of the reticuloendothelial system *is con*sidered as the probable cause of the anemia and the tendency toward inflam

DIAGNOSIS

Diagnosis is made by demonstration of the parasite in lesions by smear or culture

TREATMENT

Treatment is similar in general to treatment of American skin leishmaniasis As a rule, however, the disease can be cured with only locally applied drugs Penicillin is very effective

VISCERAL LEISHMANIASIS

GEOGRAPHICAL DISTRIBUTION

The disease is found in some regions of India, as in Calcutta in the Brahmaputra basin in Bengal Assam and the southern part of India it also exists in North China and in Indo China In *Africa* the disease occurs not only in the region of the Mediterranean (Morocco, Algeria Tunis, Tripoli, Egypt), but also farther south in Abyssinia Sudan Kenya, and Nigeria

In Europe it is disseminated throughout southern Russia The Mediterranean area has numerous foci in Yugoslavia Turkey *Greece* southern Italy southern France and Spain Some years ago it was the general belief that in the *European* foci the disease was limited to infancy Recently however, numerous cases have been described in adults

America—The disease has been observed as autochthonous only in South America As has been pointed out the first cases were described in Paraguay and in the Chaco Later numerous cases were observed in Brazil E Chagas and A W Chagas (1938) saw some cases in the Mato Grosso Barros and Rosenfeld (1942) described two cases *in* São Paulo one a patient from Bolivia the other from Ceara In America the disease is always sylvan and sporadic it does not occur in urban zones but only in rural regions and in the jungle

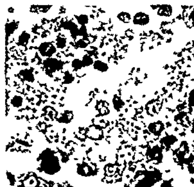

Fig 90—*Leishmania donovani* in spleen puncture (Courtesy of Oscar Felsenfeld)

ETIOLOGIC AGENT

Visceral leishmaniasis is caused by *Leishmania donovani* (Laveran and Mesnil 1903) It has the same morphology as the two species discussed above

The disease is known by a number of names in different regions in India it is known as kala azar (black fever dumdum fever or tropical splenomegaly), in the Mediterranean regions it is known as infantile kala azar or splenic anemia of children, and in South America it is called American visceral leishmaniasis or American kala azar

sive Edema, gastric disturbances and intestinal upsets and small hemorrhages of the nasal and oral mucosa are present Some infections develop acute progressive characters and death may follow at the end of a few weeks or during the first months after initiation of the disease At other times the disease tends from the first stage toward a chronic character, and it may be prolonged for several months or even years

Opinion of authors who have studied this disease is that the lesions in or on the skin constitute the so called "post kala azar dermal leishmaniasis" Such lesions appear some years after the acute state and appear as depigmented areas or in nodule form

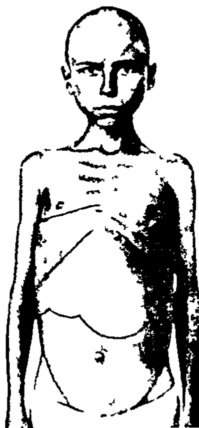

Fig 92—Clinical case of American visceral leishmaniasis (After Chagas E et al Mem Inst Oswaldo Cruz July 1937)

TRANSMISSION

Transmission of *L donovani* occurs through bite of a Phlebotomus which has been infected by biting a diseased man or animal

Transmission has recently been *accomplished (Smith et al* 1940 1941) through the bite of the Phlebotomus The mechanism is a partial or complete blocking of the proventricle and of the esophagus by the leptomonas forms a

matory complications which these patients present The spleen is enormously enlarged the capsule thickened There is a perisplenitis The spleen is congested dark red in color and firm in consistency Microscopically the sinuses of the spleen are dilated with great increase in the number of endothelial cells containing numerous leishmanias A great number of endothelial cells of the vessels are found to be parasitized The liver appears to be equally enlarged Microscopically the cells of the liver are atrophied and degenerated Fatty degeneration is present to a greater or less extent Here as in the spleen the most notable lesion consists in the presence especially in the hepatic sinusoids of numerous endothelial cells densely parasitized by Leishmania Numerous endothelial cells of other vessels become inflamed and contain parasites In advanced cases an increase of fibrous tissue with destruction of parenchyma occurs The bone marrow becomes red and friable and contains numerous macrophages filled with leishmanias as well as neutrophiles containing many of the parasites The lymphatic glands are enlarged and within them parasitized cells can be demonstrated The intestine is often ulcerated the submucosa becoming infiltrated with numerous macrophages filled with leishmanias especially numerous about Peyer s patches

Progressive leucopenia with relative and absolute lymphocytosis is seen in the blood

SYMPTOMATOLOGY

The principal symptoms of kala azar are enlargement of the spleen and often of the liver progressive emaciation anemia and a type of irregular fever Other symptoms may occur such as enlargement of the lymphatic glands pigmentation of the skin and edema The period of incubation varies according to authorities from six weeks to six months After the period of incubation the fever appears as the initial symptom In the first few weeks and sometimes during the first few months the fever reaches high levels (38° to 39° C) and may be continuous or intermittent In the greater number of cases however it is irregular In more advanced stages of the disease the fever becomes very irregular and there may be long periods of apyrexia followed by days and even weeks of pronounced thermal elevation

Emaciation is constantly present Always present in early stages it becomes progressively more alarming at the end of a few months of the disease the patient shows extreme malnutrition As a consequence of the anemia the patient s skin and mucous membranes are very pale In some cases there is change in the color of the skin resulting in characteristic darkening

An increase in volume of the spleen is a very early symptom the organ sometimes attaining enormous proportions reaching to the symphysis pubis Its consistency is very hard so that it is known in leishmanial zones of Brazil by the expression hard as a board (E Chagas) In many regions of South America where the disease has a high incidence splenomegaly caused by malaria is confused with that caused by leishmaniasis For this reason physicians until recently have not always been able to make a clinical diagnosis of leishmaniasis There is hepatomegaly which may be very exten

With *reference to epidemiologic characteristics* of American visceral leishmaniasis it has been proved according to studies made by the F Chagas Commission (1938) that the disease is sporadic and does not assume the *epidemic character observed in Indian kala azar* Its cradle is the forest since it does not occur in urban but in rural districts Although it is primarily a disease of early childhood (1 to 2 years) cases have been found in youths *and adults*

DIAGNOSIS

Clinical—Differential clinical diagnosis should be made from malaria and schistosomiasis If the patient does not improve under quinine treatment malaria may be excluded from consideration Demonstration of the eggs of Schistosoma will confirm a diagnosis of that helminthiasis

Laboratory Methods—These may be direct by examination for the parasites or indirect by serologic reaction Microscopic preparations can be used to demonstrate the parasites in the blood the spleen the bone marrow or the liver These preparations are stained with Giemsa or other methods

The leucopenia may be of great diagnostic value

Blood—Examination of peripheral blood reveals parasites in the leucocytes Since these are difficult to find the blood should be diluted with an oxalate solution and immediately centrifuged in a special container After sedimentation the layer of leucocytes is drawn off with a pipette Histiocytes containing many organisms are easily found A blood culture may be made

Puncture of the Spleen—Puncture of the spleen is the method of choice in the search for leishmanias According to Chagas et al (1938) this method gives the best results in diagnosis It has proved to be quick and efficient in all phases of the disease and practically innocuous To make the puncture a needle 10 cm long and 2 mm in diameter is introduced below the costal margin and at a distance which varies with the type of spleen Generally parasites are found in smears from the splenic pulp in great numbers when the case is recent In the period of the " state of disease " leishmanias are less numerous and for the most part extracellular The pulp may be used to prepare cultures of the parasites

Puncture of the Liver—Resort to puncture of the liver is less frequent than splenic puncture since hepatomegaly occurs later in the disease than does splenomegaly Finding parasites in the liver is more difficult than finding them in the spleen

Bone Marrow Puncture—Usually the sternum is selected when a search for parasites is to be made in the bone marrow They are frequently found In China puncture of the sternum is the method of choice in the diagnosis of the disease in hospitals dispensaries and rural posts It is easier and less dangerous than splenic puncture and may be repeated several times

Indirect Methods—Serologic methods are used quite frequently Some of the principal tests are

Formol Gel Test (Aldehyde Reaction)* This test was used by Gaté and Papacostas (1920) for syphilis but it has been discarded here because of its

*Editor's note (O F) The Chopra Napier test, consisting of the addition of a pentavalent antimony to the blood is little used

fact similar to that which occurs in fleas infected with plague bacilli Hamsters and mice exposed to the bite of the blocked Phlebotomi acquire the disease

In Brazil very few investigations have been made with respect to the possibility of transmission of *L donovani* by our species of Phlebotomus Ferreira Deane and Mangabeira Filho (1939) proved the presence of leptomonas forms in two specimens of *P longipalpis* captured while sucking on a dog which was naturally infected Chagas (1940) succeeded in infecting 75 per cent of the specimens of *P longipalpis* and 75 per cent of *P intermedius* by feeding on a parasitized dog Paraense and A W Chagas (1940) succeeded in transmitting the disease to a hamster by inoculation with a triturate of *P intermedius* which had been experimentally infected

Other vectors are *P argentipes* *P chinensis* *P langeroni* *P major* *P perniciosus* and *P sergenti*

As to the mechanism of transmission it has been shown that *L donovani* develops in the digestive tube of the Phlebotomus in the leptomonas form It migrates to the anterior portion of the pharynx and buccal cavity in six to nine days after the Phlebotomus has sucked on an infected individual it is believed that the Phlebotomus is not infectious until this time

Another possible method of transmission is the ingestion of food or beverages contaminated with *L donovani* This parasite may be found in feces urine nasal secretions, sputum and saliva of patients with kala azar This method of transmission however is of little practical importance

Shortt Craighead Smith and Swaminath (1930) showed the possibility of contact infection They placed healthy hamsters in the same cage with six experimentally infected hamsters Two of the normal animals developed a severe infection with *L donovani*

Natural Infection in Animals

The dog since it is often found naturally infected chiefly in the Mediterranean region and in China is considered a natural reservoir of the disease On the other hand in India human disease is not associated with dogs The natural disease in dogs as in man runs an acute or chronic course with loss of weight fever anemia and enlargement of the spleen and liver The animals may succumb to this parasitosis or to an intercurrent infection but spontaneous cure occurs more often in dogs than in human beings

In Brazil Chagas et al (1938) found visceral leishmaniasis in seven dogs and one cat as well as in other wild animals Dogs with visceral leishmaniasis frequently have cutaneous lesions Chodukin and Sofieff (1930) concluded that these lesions in dogs are a symptom of a generalized infection Richardson (1925) found a horse and de Paolis a sheep naturally infected with leishmania identical with *L donovani* In Russia gerbils are naturally infected

EPIDEMIOLOGY

In the Mediterranean region the infection is most common in children from 1 to 4 years of age while in India the youths are affected although in both regions infection occurs both in adults and in infants As to sex men are more frequently infected than are women

in the treatment of visceral leishmaniasis Chopra (1936) regarded Neostibosan and Urea stibamine as the best of these preparations

Neostibosan (diethylamine p aminophenol stibinate) contains about 40 per cent antimony Each injection of 6 c c contains 0 30 Gm and is given intramuscularly It is the less toxic of the pentavalent antimonials and is especially indicated in the treatment of the disease in children

Aromatic diamidines are being used experimentally in therapeutics They must be used cautiously because of their neurologic action Best results have been obtained with Stilbamidine (4 4'diamido stilbinate)

PROPHYLAXIS

As with *L brasiliensis*, prophylaxis consists of campaigns against the Phlebotomus and of prevention of bites by these diptera Since the infection can be transmitted in feces and urine the possibility of transmission through contaminated food should be taken into consideration An important prophylactic measure is the elimination of dogs which serve as reservoirs of the parasites in endemic regions

Cerqueira A 1885 In Cerqueira A C de Castro (1914)

lack of sensitivity Spackman (1921) however noticed that the serum of a patient with kala azar becomes coagulated in a few seconds and not in a few hours as in the test of Gaté and Papacostas

Place 1 c c of the patient s serum free from erythrocytes in a 9 mm. test tube
Add 1 drop of 40% (commercial) formaldehyde
A positive result is indicated by complete coagulation of the serum Coagulation is complete if the serum does not move when the tube is inverted or shaken One hour is allowed for the coagulation process

According to Chagas et al (1938) the test like other serologic tests is not absolutely specific While it is always negative in normal individuals solidification of the serum takes place in other diseases besides kala azar—malaria leprosy bouba and alastrim—although the process takes a long time In American visceral leishmaniasis the reaction is slow in the early stages but increases in rapidity with the degree of infection It is useful in diagnosis of American visceral leishmaniasis in the early stages and also it can be used for evaluating the results of therapy

Brahmachari Test (Reaction of Ray) This consists of the formation of a turbid ring at the point of contact between the serum and distilled water

Allow 2 or 3 c c of distilled water to flow slowly along the walls of a test tube containing 1 c.c. of serum
A turbid ring forms at the point of contact in positive cases the stronger the reaction the more definite the ring

E Chagas et al (1938) used the Brahmachari test in fifty two cases of American visceral leishmaniasis with results similar to those obtained in the formol gel test The reaction is due to increase of globulin principally euglobulin in the serum with corresponding reduction in albumin The reaction is not specific for kala azar but occurs as well in malaria

Other Tests*—Tests using peptonate of iron or Sulfarsenol of Cammino petros etc are little used Complement fixation was especially studied by Moses (1919) and Marques da Cunha and E Dias (1939) They used as antigen cultures of leishmanias washed in physiologic solutions by centrifugation and preserved in acetone for a few days After evaporation of the acetone the leishmanias which remained were triturated and mixed with ethyl alcohol Positive results were obtained with this antigen not only for visceral and cutaneous leishmaniasis but also for Chagas disease This fact has been interpreted as the result of group reaction It is a delicate test and is not readily adaptable as a routine measure

Recently antigens prepared from acid fast organisms are used for complement fixation tests

For intradermal skin tests see Mucocutaneous Leishmaniasis

TREATMENT

In addition to antimonials mentioned above with reference to *L brasiliensis* some pentavalent derivatives of antimony have proved efficacious

*See also Chapter *

in the treatment of visceral leishmaniasis Chopra (1936) regarded Neostibosan and Urea stibamine as the best of these preparations

Neostibosan (diethylamine p aminophenol stibinate) contains about 40 per cent antimony Each injection of 6 c c contains 0 30 Gm and is given intramuscularly *It is the less toxic of the pentavalent antimonials and is especially indicated in the treatment of the disease in children*

Aromatic diamidines are being used experimentally in therapeutics They must be used cautiously because of their neurologic action Best results have been obtained with Stilbamidine (4 4′diamido stilbinate)

PROPHYLAXIS

As with *L braziliensis*, prophylaxis consists of campaigns against the Phlebotomus and of prevention of bites by these diptera Since the infection can be transmitted in feces and urine, the possibility of transmission through contaminated food should be taken into consideration *An important prophylactic measure* is the elimination of dogs which serve as reservoirs of the parasites in endemic regions

CHAPTER 11

PINTA, MAL DEL PINTO, OR CARATE

FRANCISCO LEÓN BLANCO AND ELVIRA SÁNCHEZ GARCÍA

The first European to use the word "carate" was Gonzalo de Oviedo y Valdez In his work, written between 1505 and 1516, he states that in Castilla del Oro (the region corresponding to present-day Panama and Colombia) the term "carate" was used to designate a certain cutaneous affection which appears to be that which we know today as "pinta," "mal del pinto," and "carate" Thus this disease was *in existence on the American continent before the conquest*, and the word "carate" is of Caribbean origin

"Pinta" is a Spanish word which is used to describe the spotted or mottled appearance of some animals The phrase "mal del pinto" signifies "spotted sickness" or "spotted disease" In Spanish American countries a number of common names are used in speaking of the disease, but there is a growing tendency to use only the words "pinta" or "carate" and the phrase "mal del pinto" to describe the disease and the words "pintous" (pinto) and "caratous" (caratosa) to designate those who are affected with the disease

HISTORY

McClellan (1825) brought this disease to the attention of the Anglo Saxon medical world and called it *pinta* Alibert (1829) made it known under the name *carate* In the past century, the most important contributions to the knowledge of pinta were made by León (1862), Gómez (1879), Ruiz Sandoval (1881), Iryz (1881), and Montoya Florez (1889) *Ruiz Sandoval and Iryz, working simultaneously although independently*, were the first to consider pinta a dermatomycosis A great impetus was given to this theory in later years by Montoya Florez (1898)

Gratz (1913) discovered that salvarsan acted as a specific in carate This impor tant [illegible] and [illegible] the [illegible] lieved that patients with carate were also infected with syphilis or pian (yaws) González Herrejón and Pallares, however, considered the positive serologic test characteristic for mal del pinto *This fact and others served as a basis for his theory that mal del pinto is a* treponematosis different from syphilis and from yaws

Alfonso Armenteros, Grau Triana, and León Blanco found the treponemata in a Cuban case of pinta (1938) León Blanco (1938 1942) demonstrated the constant presence of *treponemata* in Mexican cases of pinta, and the specificity of these organisms

León Blanco described the initial lesion and the early lesions of pinta thus completing the knowledge of the developmental cycle of the affection

Fox (1928 1930), Grau Triana (1937), González Herrejón (1927 1938), Latapi and León Blanco (1940), Pardo Castelló and Ferrer (1942), and Oteiza (1945 1946) also made important contributions to the knowledge of pinta

CHAPTER 11

PINTA, MAL DEL PINTO, OR CARATE

Francisco León Blanco and Elvira Sánchez García

The first European to use the word "carate" was Gonzalo de Oviedo y Valdez. In his work, written between 1507 and 1516, he states that in Castilla del Oro (the region corresponding to present day Panama and Colombia) the term "carate" was used to designate a certain cutaneous affection which appears to be that which we know today as "pinta," "mal del pinto," and "carate." Thus this disease was in existence on the American continent before the conquest and the word "*carate*" is of *Caribbean origin*.

"Pinta" is a Spanish word which is used to describe the spotted or mottled appearance of some animals. The phrase "mal del pinto" signifies "spotted sickness" or "spotted disease." In Spanish American countries a number of common names are used in speaking of the disease, but there is a growing tendency to use only the words "pinta" or "carate" and the phrase "mal del pinto" to describe the disease and the words "pintous" (pinto) and "caratous" (caratosa) to designate those who are affected with the disease.

HISTORY

McClellan (1825) brought this disease to the attention of the Anglo Saxon medical world and called it *pinta*. Alibert (1829) made it known under the name *carate*. In the past century, the most important contributions to the knowledge of pinta were made by León (1862), Gómez (1870), Ruiz Sandoval (1881), Iryz (1881), and Montoya Florez (1889). Ruiz Sandoval and Iryz, working simultaneously although independently, were the first to consider pinta a dermatomycosis. A great impetus was given to this theory in later years by Montoya Florez (1898).

Gratz (1913) discovered that salvarsan acted as a specific in carate. This important contribution of Gratz passed almost completely unnoticed. Menk (1926) in Colombia and González Herrejón and Pallares (1927) in Mexico, working independently, discovered that the Wassermann reaction is positive in a high percentage of cases with carate. Menk believed that patients with carate were also infected with syphilis or pian (yaws). González Herrejón and Pallares, however, considered the positive serologic test characteristic for mal del pinto. This fact and others served as a basis for his theory that mal del pinto is a treponematosis different from syphilis and from yaws.

Alfonso Armenteros, Grau Triana, and León Blanco found the treponemata in a Cuban case of pinta (1938). León Blanco (1938 1942) demonstrated the constant presence of treponemata in Mexican cases of pinta, and the specificity of these organisms.

León Blanco described the initial lesion and the early lesions of pinta, thus completing the knowledge of the developmental cycle of the affection.

Fox (1928 1930), Grau Triana (1937), González Herrejón (1927 1938), Latapí and León Blanco (1940), Pardo Castelló and Ferrer (1942), and Oteiza (1945 1946) *also made* important contributions to the knowledge of pinta.

ETIOLOGY

Experimental studies by Leon Blanco established the causative agent of pinta as a treponema, he proposed that it be named *Treponema herrejoni*, in honor of the Mexican scientist who had contributed so much to the knowledge of pinta. A few days prior to this proposal Brumpt suggested the name *Treponema carateum*, and according to the rules of priority the latter is the valid name of the species all other names being synonyms.

The characteristics of this treponema (León Blanco) are as follows. When viewed against a dark background it appears as a brilliant cylindrical filament, coiled in a spiral about an imaginary longitudinal axis. The coils of the spiral are tight, regular, and rigid, especially in the center. At times these coils relax and separate to return to their original position just like a steel spring which if pulled apart by both ends, quickly resumes the original position when released.

Fig. 93.—Photomicrograph of *Treponema carateum* (Krajian spirochete stain). Section of skin from autoinoculation with *T. carateum*. (Courtesy of R. I. H. Grauwohl.)

The motility of *T. carateum* is as marked as that of *T. pallidum* of syphilis. It turns rapidly about its longitudinal axis. Its movements of progression are bipolar: it can advance or retreat with equal facility. If it remains stationary, in addition to its spinning or drilling movements, one notices movements of torsion and flection, arching and assuming the shapes of the letters O, P, or S. It also has an unduiant or creeping movement in which the whole body of the treponema participates so that it resembles the movement of a wave of contraction. The organism moves in and out of focus.

After one to six hours, according to the surrounding temperature, the treponema slowly loses its movements until these completely cease. At this time the coils seem to become looser or wider and the body of the parasite then looks like an undulant ribbon in a single plane.

The treponema stains well with Giemsa stain or with aniline dyes. With aniline dyes it is necessary to use a mordant, tannic acid or potassium permanganate. With Giemsa stain the treponema stains a uniform pale rose color. The Krajian and the Fontana Tribondeau methods as used for staining treponemata of syphilis give the organism a black or dark chestnut color.

The methods of Jahnel, Warthin-Starry, and Dieterle also stain the treponemata in tissues very well.*

The organism varies in length between 7 and 22 microns. The average of a large number of measurements is 17 microns. Thickness is approximately 0.2 to 0.3 micron. Depth of the spirals is 0.8 to 1.0 micron. The number of spirals varies according to the length: short specimens have 7, longer ones 15 to 20 spirals.

After several hours of contact, 10 per cent saponin entirely dissolves the treponemata. Bile and 10 per cent sodium taurocholate have the same action. Distilled water causes them to swell.

The treponemata are killed by temperatures of 50° C for fifteen minutes; at 41° C they die within one or more hours.

León Blanco and Oteiza (1945) have recently succeeded in producing pintous scrotal chancres by experimental inoculation of rabbits. Pathogenicity to other animals is not known.

The organisms have not as yet been cultivated.

The distribution of the treponemata in cutaneous lesions in man varies for the initial lesions and pintids and also for lesions of the later phase. In the initial lesions and in the pintids, treponemata are particularly abundant in the epidermis and in the intercellular spaces of the rete mucosum, especially in the acanthotic interpapillary crests as well as in the epithelial portion of the pilosebaceous follicles. In the dermis they are localized especially in the portion occupied by the inflammatory infiltration and they are very abundant near the blood vessels; it is not exceptional to observe them as they traverse the walls of these vessels.

In lesions of the later phase we have never been able to find them in any place other than the rete mucosum and in the epithelial portion of the pilosebaceous follicles.

EPIDEMIOLOGY

Pinta is endemic in rural or suburban areas, stopping at the outskirts of large cities, particularly in countries with a high endemic index. In countries with only sporadic cases, the disease can be found in large urban centers.

In the intertropical regions of the Americas (Mexico, Guatemala, Colombia, Venezuela, Ecuador, Peru, Brazil), the disease is most widely distributed in villages situated in the valleys of large rivers at an altitude which varies from sea level to 2,570 meters (Chillos Valley in Ecuador). In this extensive zone there are places in which the index of infection reaches 50 to 90 per cent (pintogenous zones). There are other localities, situated a short distance from these zones, in which the disease attacks scarcely 1 to 2 per cent of the inhabitants. The cause of this unequal distribution is not clear, but there seems to be one definite factor known about its incidence—*there is no relationship between the disease and geographic conditions.*

*The editor (R. B. H. G.) prefers the Krajian twenty minute stain for spirochetes in smears and tissues (see Chapter 70).

ETIOLOGY

Experimental studies by Leon Blanco established the causative agent of pinta as a treponema, he proposed that it be named *Treponema herrejoni*, in honor of the Mexican scientist who had contributed so much to the knowledge of pinta. A few days prior to this proposal Brumpt suggested the name *Treponema carateum*, and according to the rules of priority the latter is the valid name of the species, all other names being synonyms.

The characteristics of this treponema (Leon Blanco) are as follows. When viewed *against a dark background it appears as a brilliant cylindrical filament coiled in a* spiral about an imaginary longitudinal axis. The coils of the spiral are tight, regular and rigid, especially in the center. At times these coils relax and separate, to return to their original position just like a steel spring which, if pulled apart by both ends, quickly resumes the original position when released.

Fig 93.—Photomicrograph of *Treponema carateum* (Krajian spirochete stain). Section of skin from autoinoculation with *T carateum*. (Courtesy of R I H [illegible])

The motility of *T carateum* is not unlike that of *T pallidum* of syphilis. It turns rapidly about its longitudinal axis. Its movements of progression are bipolar; it can advance or retreat with equal facility. *If it remains stationary*, in addition to its spinning or drilling movements one notices movements of torsion and flection, arching and assuming the shapes of the letters O, P or S. It also has an undulant or creeping movement in which the whole body of the treponema participates, so that it resembles the movement of a wave of contraction. The organism moves in and out of focus.

In Colombia, carate is endemic in all the valleys and especially in the valleys of the great rivers According to Pena Chavarria and Shipley (1925), there are approximately 400,000 cases of carate, although in reality a census of patients has never been carried out This number corresponds to 6 per cent of the total population

Caratogenous zones with the greatest endemic index are found in the valleys of the Magdalena and Cauca rivers, the valleys of Patia and San Juan rivers are of less importance According to the same authors, departments or districts with the highest incidence are Huila, Magdalena, Tolima, Antioquia, Cauca Valley, Bolivar, Antlantico, Caldas, North Santander, South Santander, Boyaca, Cundinamarca, and Nariño

In Venezuela there are about 50 000 cases of carate (Iriarte, 1940) distributed throughout the states of Barinas, Apure, Mérida, Táchira, Trujillo, Lara, Zulia, Portuguesa, Falcon, Bolivar, Yaracuy, Carabobo, and the territories of Amacuro and Amazonas

According to L. A Leon (1940), there are four pintogenous zones in Ecuador, with about 5,700 cases These zones are the valley of the Chillos (pintogenous zone situated at a higher altitude, 2,570 meters above sea level) in the Province of Pichincha, Santa Rosa de Machala, in the Oro Province, Catamayo Valley in the Province of Loja, Archidona, Tena, and Napo, in the Province of Napo Pastaza According to the same author, the disease is highly distributed among the Salasac Indians in the Province of Tungurahua.

There are not even approximate data on the extent of the disease in Peru According to Hercelles (1903), cases of pinta are seen in the District of Suyo, Province of Ayabaca (Department of Piura), in the city of Lima, in Carabaillo, and in Aucayama (Department of Lima), in Palpa, Nazca, Pámpano, and Humay (Department of Ica), in the Majéso Valley of the Province of Castilla, and in the towns of Huancarqui and Uraca (Department of Arequipa) Escomel (1931) has indicated that there are cases in Tambo, Victor, Siguas, Camaná, and in the valley of the Madre de Dios River Weiss (1942) has pointed out the presence of cases in Yarimaguas (Department of Loreto)

In Bolivia Ventemillas (1944) indicated that cases of carate are found in villages situated near the Guapay or Rio Grande river, and Aliaga Suárez, cited by Suárez (1944), has described four pintogenous zones in that country near the Chapare, Rio Grand or Guapay, Madre de Dios, and Heath rivers, to which Suárez adds a fifth, the valley of the Beni River

In Brazil, according to Langeron, there are many cases of carate in the state of Amazonas and in the valleys of the Purus and Juruá rivers In these regions, entire tribes of Indians are affected Silva (1940), Souza Araujo (1940), and Padilha (1944) have identified Brazilian puru puru with pinta

Escobar P (1945) has thoroughly studied and reported cases in Guatemala, these patients coming from the capital, from San Agustin Acasguastlán, from Frajines, Jiquimulilla, and El Molino The extent of the disease in that country is not definitely known, but we assume that the endemic index should be high in zones which border Chiapas (Mexico)

In Honduras the disease was first reported by Lazo Arriaga (1885). In that country it seems to be extensive In British Honduras (Belize) almost all indigenous adults suffer from the disease, according to Browne (1900), according to Cran (1900) not less than 60 per cent of the native population is caratous

In the Republic of San Salvador, Barrientos and his collaborators (1941) reported sporadic cases of pinta

In the United States Lieberthal (1943) and in Argentina Fonso Gandolfo and Rugiero (1942) and Fernández and collaborators (1945) reported cases with cutaneous syndromes similar to those of pinta, with positive or negative serologic reactions But the fact that both of these countries are so far from the zones of endemic pinta and the fact that pintoid cutaneous syndromes caused by syphilis have been described (Lacapare, 1923), plus the fact that it has been demonstrated experimentally that syphilis can produce such syndromes (León Blanco, 1942), inclines us to accept with definite reservations the cases reported in the United states and Argentina as genuine cases of pinta

The index of infection is higher among inhabitants of villages and small towns situated between mountainous zones and the sea than among inhabitants of towns which lie near the coast. In coastal zones rural towns and villages show a higher index of infection than less urbanized areas.

In highly infected villages the disease occurs in family foci. However, intimate contact with pintous patients is not the sole prerequisite for infection, since it is frequently observed that in marriages of one to twenty five years one marital partner may be ill with the disease while the other has remained healthy.

In countries in which pinta is sporadic the infection is not transmitted to those who live with infected individuals.

It has frequently been stated that Indians, Negroes and those of mixed blood (mestizos—offspring of a European and an Indian or Negro) are more susceptible to pinta than the white race. This is not entirely correct, because members of the white race are equally infected when they live under the same conditions as the others. If in Mexico the Indians and mestizos form the largest group of patients with pinta, it is only because they are the dominant population group in the localities where the disease is prevalent. In the Catamayo Valley (Ecuador), where approximately 30 per cent of the population is infected, the disease is found principally among Negroes. There is a somewhat similar situation in Colombia. There is no special susceptibility to pinta on the part of certain races when the mode of life is identical.

Sex has no bearing on the incidence of the disease, at least not in Mexico.

Pinta can occur at any age, but the initial lesion is most often seen in persons between the ages of 5 and 20 years (León Blanco).

GEOGRAPHIC DISTRIBUTION

Pinta or carate has until recently been considered an infection peculiar to countries of the intertropical zones of the Americas. This idea has been challenged since cases thought to be pinta have been found in the United States (Lieberthal 1943) and in Argentina (Fonso Gandolfo and Rugiero 1942, Fernández and collaborators 1945). Pinta may exist in American countries which up to now had been thought to be free from the disease, and also on other continents.

In Cuba, cases of pinta are sporadic and come from the six provinces, in none of which pintogenous zones or foci have been described. It should be emphasized that some of these patients have always lived in the capital of the Republic, and that in a large majority of the cases they have not transmitted the disease to those who live with them. Although the exact number of cases cannot be stated, they have not exceeded 100 to 120.

In Mexico, according to the First Census of Mal del Pinto carried out by the Department of Public Health, there are approximately 2 0 685 cases, a conservative figure if we consider that at the time of the census (1929-1932) the initial lesion and pintids were as yet unknown.

The principal pintogenous zone in Mexico is the vast geographic depression formed by the valley of the Balsas River, including the northwestern part of Oaxaca, Northern Guerrero, a part of Veracruz and almost the whole of Morelos, also the southern part of the states of Mexico, Puebla and Michoacán. Of less importance are zones in the states of Nayarit, Campeche, Tabasco and Chiapas. If we consider the number of inhabitants in Mexico, 1.5 per cent of the total population is attacked by pinta.

Primary Phase

Initial Lesion—It has been possible to follow the initial lesion of pinta throughout its course of development in experimentally infected cases According to latest data in our possession the period of incubation from the time of inoculation to the appearance of the initial lesion varies between seven and sixty days In some cases the lesion appears early, seventy two hours after the inoculation

After the stated period of incubation a rose colored spot punctiform or lenticular appears at the point of inoculation After two or three days this becomes infiltrated assuming an aspect of a rose colored papule oval or hemispherical in shape which stands out in relief 1 to 3 mm from the skin

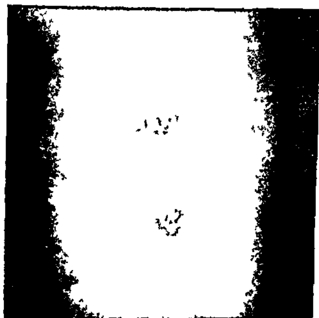

Fig 94 —Experimental double initial lesion approximately 30 days after inoculation Papular phase papules irregular infiltrated covered with scales Inoculum is from one Cuban and one Mexican case Observe identity of development and clinical aspect

or, it may take the form of a slightly infiltrated erythematous small plaque barely raised above the surface of the skin pinkish shiny, and covered slightly with furfuraceous scales The initial papule grows slowly, and invariably, after thirty to fifty days it assumes the appearance of a nummular erythematosquamous plaque clearly outlined against the healthy skin infiltrated to a greater or lesser degree pink and covered with laminar or furfuraceous scales At times the scales in the periphery become partially detached and form a sort of "collar" about the initial lesion In dark skinned individuals it takes on a slate colored hue due to accumulations of pigment in the dermis In very scaly lesions when the stratified scales are carefully removed a shiny surface is seen beneath, sometimes oozing slightly, smooth

Yaws is extensive in Santo Domingo and Haiti It is not definitely known whether this disease can cause pintoid cutaneous syndromes For this reason, there is no assurance that the disease described in Haiti by Audain (1905) under the name "boussarole" is pinta or yaws The same may be said concerning the Dominican "busarola" which is very abundant in Paraje de Malgaren, Province of Seibo

Browne (1901) states that the affection exists along the Gold Coast (Africa) where, on the other hand, yaws is endemic But it is not known whether the affection to which Browne refers (and which the natives according to this author, call "tungere") is pinta or yaws The case described by Bettolo (1940) in Italian East Africa may be vitiligo

Cases described by Madden and Goodman (1900) in Egypt and by Edgar (1901) and by Edgar and Boddaert (1901) in the Malay Peninsula are very atypical and at the time that they were diagnosed, the etiology of pinta was as yet unknown This same statement may be made concerning the case described by Woolley (1904) in the Philippine Islands

SYMPTOMATOLOGY

The experimental work of Leon Blanco and his co workers in the extensive pintogenous zone of the state of Guerrero (Mexico) has demonstrated that pinta begins with an initial lesion, followed after a rather long period of time by scattered cutaneous lesions with clinical characteristics distinctly like those classically known

It seems clear that spread of the treponemata from the initial lesion takes place through the lymphatics or the blood stream The spread of treponemata to neighboring lymph glands takes place in a very early period of the infection However, cutaneous manifestations which indicate clinically the generalization of the infection do not appear until two to four months after the initial lesion, and sometimes not until one or more years later During all this time, the initial lesion is a single cutaneous lesion and serologic reactions remain negative in most cases

From the time of appearance of the first disseminated cutaneous lesions, serologic reactions become positive in a large percentage of the cases The longer the period of development of the disease, the higher the percentage of positive cases From this period, serologic reactions remain constant and strongly positive during the entire course of development of pinta On the other hand, treated cases show negative reactions during the early stages of the disease But after pinta has been developing for years, the serologic tests are unchangeable, even when intensive treatment has been carried out Moreover, the disseminated cutaneous lesions of the early stages of the development of pinta differ clinically from a dermatologic point of view, from the later stages

These facts have led us to conclude that there are two periods in the development of pinta the *primary phase* and the *phase of generalization* In the phase of generalization, two phases may be distinguished, an *early* phase and a *later* phase The study of the symptomatology of pinta, therefore will be divided into three parts The first part will deal with the *initial lesion*, the second, with lesions of the early phase of the period of generalization *(pintids)*, and the third, the lesions of the later phase of the period of generalization *(dyschromic phase)*

colored dots corresponding to small dilated blood vessels filled with blood. Frequently tiny drops of yellowish serous substance, rich in treponemata ooze from the open surface.

Trichophytoid Type.—At times the initial lesion takes on the appearance of perfectly circular erythematosquamous plaques with elevated borders formed by confluent papules. The central portion is of a homogeneous or slightly pigmented pink color and is covered with fine scales. Sometimes, due to partial healing, isolated islands of normal or but slightly pigmented skin are observed within the plaque. These areas are separated by slightly raised pink borders, giving a petaloid appearance to the lesions.

Fig. 96.—Double experimental initial lesion in erythematous squamous phase. Circular discs 3.5 cm. in diameter, infiltrated, with raised border furrowed by deep wrinkles and covered with transparent laminar scales. Inoculum taken from a Cuban case. *Ninety-two days after inoculation.*

Lichenoid Type.—This is characterized by nummular plaques which may be as large as the palm of the hand, irregular in outline, with slightly raised borders. The surface of this plaque presents a shiny cross-hatched appearance due to exaggeration of the natural wrinkles of the skin. The color varies in different subjects, but slate colored tints predominate. Scraping with a curette or spoon detaches adherent scales.

or furrowed by more or less deep wrinkle like folds Around it a hypochromic halo with furfuraceous scales is frequently observed

The surface of the initial lesion continually increases in size although very slowly, by steady excentric growth or by the appearance in the periphery of neighboring papules which fuse with the original plaque as they grow Circular or oval plaques of festooned or circinate contour result from this They retain their erythematosquamous aspect for a long time

In the experimental as well as in the naturally acquired disease the initial lesion develops as the only lesion for a long time It shows different clinical aspects according to the stage at which it is examined In pintogenous

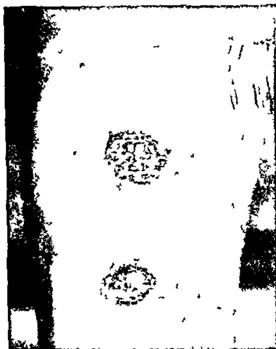

Fig 95—Double experimental lesion 60 days after inoculation Erythematous-squamous phase erythematous squamous nummular lesions covered with laminar scales partially loosened Near both lesions are satellite papules Same patient as shown in Fig 94

zones with a high index of infection there is opportunity to see many patients with initial lesions The lesions in these cases while retaining the fundamental appearance of erythematosquamous plaques present a varied clinical aspect which may be reduced schematically to the following types

Psoriasiform Type—This type is formed by psoriasiform erythematosquamous plaques circular or oval 1 to 5 cm in diameter limited superficially infiltrated and covered with stratified laminar scales grayish white or yellowish white If the scales are carefully removed a pink shiny surface shows underneath slightly moist and seeded with slightly raised papules and with ruby

result in secondary infection which modifies the clinical appearance of th initial lesions of pinta to a slight degree

One or two of the regional glands are almost always enlarged after th initial lesion has been developing for some time In experimental cases th enlarged gland is almost always discrete the diseased gland or glands are har moveable painless about the size of a small bean In the fluid obtaine by puncture treponemata are constantly found upon dark field examinatio

In naturally infected cases we have almost invariably observed one glan enlarged rather markedly this we attribute to superimposed secondary infe tion It is frequent in this type of patient and is due to negligenc

ended to the entire lo er It is formed by one sole slate co ored zones due to loosened Approximately

Early Lesions of the Period of Generalization

Pintids—Although experimental proof is lacking it is evident that dis semination of treponemata from the initial lesion to the various regions of the skin takes place through the blood stream or the lymphatics Localization and multiplication of the treponemata in the skin is manifested clinically at the beginning by a roseola or slightly infiltrated papules

The Large Plaque Type—After a development of some months the initial lesion shows large areas of geographic contours occupying an entire region of the body or at least a major portion of a region The surface is formed by a mixture of zones of normal or slightly atrophied skin pigmented hypochromic or frankly achromic along with other erythematous areas covered with laminar or furfuraceous scales and seeded with smooth or scaly papules The contours of these large plaques are polycyclic and circinate

Transition from one clinical type to another can be verified by observation of patients over a long period of time

Cuban case

The initial lesion is always localized at the site of the portal of entry of the treponema which usually means the uncovered parts of the body Of 257 cases the initial lesion was localized in 163 cases or 63 per cent in the lower third of the leg or in the back of the foot in 67 cases or 26 per cent in the forearms and back of the hand in 15 cases or 5 per cent on the face and neck in 9 cases or 3 per cent on the arms thighs and buttocks and in only one each or 0 5 per cent on the palm of the hand the sole of the foot and on the trunk

The most marked subjective symptom is pruritus In the papular phase the initial lesion is always pruriginous in varying degrees In the erythematosquamous phase pruritus is less marked and almost always intermittent Scratching induced by pruritus produces excoriations which not infrequently

neighboring elements which break out in the area and fuse with the original plaque The first method of growth results in discoid oval or orbicular plaques with a definite outline The second type of growth results in circinate plaques the borders of which are described by *intersecting arcs*

The rose colored spots or papules do not always develop toward the formation of erythematosquamous plaques In an as yet undetermined percentage of cases approximately 30 per cent dyschromic disturbances predominate over inflammation and scales and nummular or larger plaques form These vary in shading from slate blue to steel gray, or they may be hypochromic and decidedly whitish Either type may present a lichenoid appearance

For these erythematosquamous, erythematopigmentary, or erythematochromic plaques Leon Blanco has proposed the name *pintids* This terminology is generally accepted today

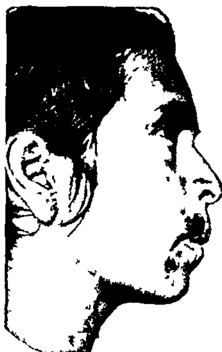

Fig 100—Erythematopigmentary pintids on face and neck The lesions are slate colored masked by erythema Infiltration is very superficial and scales are lacking Naturally acquired disease Mexican case

Sustained study of pintids over a long period of time shows that in the course of months of infiltration erythema and dyschromia are combined quantitatively in variable proportions in the different stages of development of each element This is the cause of the variation in the clinical aspects *In general* erythematosquamous pintids maintain this characteristic during the first year of their development but after this time or even later, the scales become scarce and the erythema attenuates Approximately at the end of the second year the scales usually furfuraceous are barely apparent and erythema very discrete

Between the eighth and tenth days the skin over the rose colored spots or papules up to now but slightly modified shows accentuation of the natural creases and becomes covered with furfuraceous or laminar scales giving the lesion a slightly lichenoid appearance Thenceforward the infiltration increases more or less and the plaque stands out from the surrounding area like a lozenge the scales increase the borders become prominent so that the

Fig 99 Papulo squamous pintids The papules are based on an extensive erythematous plaque which extends over the entire antero internal surface of the thigh Naturally acquired disease *Mexican case*

boundaries of the lesion as related to the surrounding skin can be perfectly seen If the scales are detached at this time a rosy surface smooth or granular may be observed By diascopy the rose color disappears and in its place is seen a whitish surface hypochromic or slightly pigmented After about thirty days the more or less circular elements reach a diameter of approximately 1 to 1 5 cm Growth of the surface takes place either by continuous centrifugal extension or by fusion of a certain number of similar

limitation The margins are generally more active than the center of the lesion In pintids which have been developing over a long period of time or in those which have been treated by topical medication the margins are broken and form intersecting arcs separated by zones of healthy or slightly atrophic skin which gives these pintids a markedly syphiloid aspect

As to their morphology numerous clinical types of pintids may be described psoriasiform gyrate annular petaloid rosette shaped or sheet like etc Because of their similarity to certain syphilodermas and leprous lesions some are described as "syphiloid" or "leproid" pintids etc

The number of pintids varies greatly in different subjects In some cases the outbreak may consist solely of one or two elements in others twenty thirty or a hundred or more may appear In either case they may be localized in the trunk or on the extremities and there is almost always a marked tendency to symmetry

The development of pintids does not occur all at once In the course of the early phase of the period of generalization new elements appear progressively and develop in a manner similar to those which appeared earlier

Pintids as well as the initial lesion may undergo spontaneous cure or at least they might not leave a clinically appreciable cutaneous lesion The disease may pass into a latent phase the sole pathologic manifestation of which is the persistently positive serologic reaction (Wassermann and Kahn) At the end of four or five years or perhaps longer cutaneous lesions begin to reappear localized in the extremities These are in the form of pigmented or achromic spots which may or may not be accompanied by palmoplantar keratoderma We have made these observations (as yet unpublished) in two cases experimentally infected They serve to explain why a certain number of Mexican cases and almost all of the Cuban cases with late manifestations give no history of antecedent initial lesions or pintids possibly the patients have forgotten that they had ever had any such lesions

With the exception of intermittent pruritus and a slight increase in painful sensations pintids present no other subjective symptoms

When the breaking out of pintids is extensive it is almost always accompanied by micropolyadenitis

Cutaneous Manifestations of the Later Phase

In a certain proportion of cases of pinta cutaneous manifestations are permanent from the time of appearance of the initial lesion to the end of life if during this time no adequate treatment has been given In other cases the initial lesion and the pintids may undergo spontaneous cure and the disease may pass into a latent phase after which cutaneous manifestations reappear especially on the skin of the distal portions of the extremities

In the first instance the initial lesion as well as the pintids slowly lose the erythematous and scaly aspect and assume the form of extensive superficial plaques of chronic atrophic dermatitis pigmented or achromic of different shapes and sizes These new elements are not as scaly or congested as the preceding ones but appear as slightly erythematous achromic or pigmented

in the central portion, is more visible in the margins. Now pigmentary changes are the predominant symptom, especially in brunette or dark skinned individuals, and superficial atrophy makes its appearance. In this manner, pintids take on an appearance of plaques that are more or less extensive, of pigmentary or achromic superficial atrophic dermatitis, circinate in contour.

The size of pintids, in general terms, is proportionate to the period of development. Recent pintids measure, on the average, about 1 cm. After a long period of development they may extend over an entire region of the body. Between these two extremes are found all intermediate sizes.

Fig 101.—Palmar pintid of the trichophytoid type. One plaque extends from the cushions of the fingers to two thirds of the anterior surface of the palm. It forms a pink superficies with small slightly achromic or pigmented areas, these last being steel colored, covered with laminar or furfuraceous scales. A similar pintid is on the other hand. Mexican case.

The shape of the pintid is as variable as the size. Up to 3 or 4 cm in diameter, they are more or less circular or oval. The large pintids are polycyclic and assume various shapes. The contour logically follows the shape of the lesion which it circumscribes, but it is usually formed by complete circles or by intersecting arcs. One of the distinctive characteristics is the perfect

face of the trunk They frequently show a slight erythematous tint and are slightly scaly *Ephelis-shaped spots and nummular areas of normally pigmented skin are usually found within the hypochromic surfaces* The margins generally well defined by normal skin describe full intersecting arcs Instead of large surfaces the hypochromic spots may appear as separate spots *the size of the palm of the hand circular or of irregular contour* scattered throughout the skin of the trunk

Generalized clinical forms which are frequent in pintogenous zones where a *high index of infection obtains* give rise to bizarre generalized dyschromias *which gives the patient a harlequin like appearance*

Fig 104 —Leucomelanoderma of the lower extremities Canities of all the hairs Perifollicular and follicular pigmented spots are of brownish or slaty color Mexican case

Because of the generalization of the cutaneous lesions this clinical form *may be considered as a universal dermatosis* the macular process extends to the face, neck trunk and extremities The lesions in each of these regions *present distinct clinical aspects* By summarizing observations of a great number of patients we may state that the lesions in a given region show two or three variations which with slight differences are repeated This being the case we shall for greater clarity *of description* describe that aspect which is generally present in lesions of the face neck trunk and extremities

spots By continuous centrifugal growth and by fusion of these elements with others the dermatosis covers progressively larger and larger areas of the skin

In a given period of time generally after a year of development pinta acquires the characteristics of a universal dermatosis At this point in the development of the disease the most apparent symptoms are achromia and pigmentation But a careful examination shows that these are constantly accompanied by superficial atrophoderma more or less extensive lichenization palmoplantar keratoderma ichthyosiform states of the lower extremities and inflammatory redness of more or less extensive zones of the skin The spotted mixture of all these lesions is a typical and distinctive characteristic of this phase which we have designated as the *late or dyschromic phase* of the period of generalization

When pinta has passed through the latent phase the lesions of the later phase are not so generalized and are circumscribed almost exclusively within the distal portion of the extremities or in certain limited regions of the trunk

After studying a large number of cases we have described from the dermatologic point of view two fundamental clinical forms of the dyschromic phase—one limited to the thorax or the extremities and the other more generalized

In *the form limited to the extremities* the typical clinical picture is symmetrical in both hands and feet Occasionally only the hands are affected or only the feet More rarely only one hand or one foot may be attacked In some cases called *crossed pintos* one hand and the foot on the opposite side of the body show typical lesions

On the dorsal surfaces of the hands and on the lower third of the surface extending along the forearms a superficial pigmented or achromic dermatitis which displays a homogeneous or spotted slate colored appearance is most frequently observed The achromic areas are situated preferentially on the skin which covers the metacarpophalangeal and interphalangeal articulations and the projections formed by the tendons of the extensor muscles of the fingers Extension of achromic areas and of pigmented areas varies widely There are cases in which achromia extends over the entire back of the hand and fingers with only small islets of pigmented skin or on the other hand slaty pigmentation may predominate with only small achromic areas These last extend to the interdigital spaces only when the entire back of the hand has been invaded

On the palmar surfaces of the hands and of the fingers there is generally achromia which can be diffused or limited to certain areas but also along the achromic zones or even within them pigmented slate colored spots of variable shape and size may be observed

In some cases the achromic spots are located on skin which appears to be almost normal perhaps slightly atrophic or scaly without slate colored pigmentation In such cases the skin surrounding the achromic spot frequently shows a slightly more accentuated pigmentation than normal recalling the leucomelanoderma of vitiligo which it greatly resembles But usually the achromia or pigmentation is accompanied by marked atrophy more or less

the other hand very scaly The erythrodermic and pigmented surfaces show intense lichenization or are markedly squamous and the pilosebaceous follicles are the sites of follicular keratosis causing atrophy and the falling out of hair

The hands may be free from or may present all the lesions which we have indicated in localized forms achromia pigmentation hyperkeratosis superficial atrophy etc The lesions have a pellagroid appearance when erythema is intense on the dorsal surfaces of the hands and when it is accompanied by atrophy and slight desquamation

Fig 105.—Leucoderma of the scrotum Dark spots correspond to normally pigmented skin Negro subject. Cuban case

In the lower extremities lesions are similar In the buttocks in the lateral surfaces of the hips and in the thighs hypochromia is often observed in areas of geographic contour which may or may not show many pigmentary carmine or slate colored spots The inner surface of the thighs is frequently spared Reticular leucoderma is often observed in the scrotum

The legs are equally the sites of hypochromia in isolated spots or over a continuous surface or there may be lead colored pigmented erythroderma In some patients the entire leg or the major portion of it is covered with a scaly stocking formed by laminar or furfuraceous scales in the last type

In the case of the *face and neck* it is almost always a question of pigmented erythroderma which extends to the whole face and neck disposed in the form of more or less extensive plaques localized in the cheekbones chin forehead and back of the nose This last formation is usually shaped like a bat In its diffused form pigmentary erythroderma may appear like a mask leaving only a narrow zone 1 or 2 cm wide below the hair line The color varies from intense blue black to lead gray with a livid tint due to erythema In members of the white race or in light skinned mestizos the pigmentation is less apparent and the face neck lobes of the ears and the back of the neck in women show a diffuse reddening Generally there is a distinct edema giving a puffed or bloated appearance to the patient s face as though he were drunk Frequently there is capillary telangiectasis

Pigmentation which at first sight appears homogeneous is formed by confluence of a series of points situated lineally along the dermic crests or around the pilosebaceous follicles

In women whose necks and presternal regions are uncovered the erythroderma takes the exact shape of the uncovered surface

On the trunk the lesions are usually hypochromic or slightly erythematous They take the form of extensive polycyclic plaques with the concavity of their contours directed toward the normal skin The surface of the lesion sometimes shows lenticular spots that resemble freckles or they may be slate colored In a general way the hypochromic areas are symmetrically disposed in the scapular and paravertebral regions separated by a wide zone of normal skin which covers the spinal column On the anterior surface of the thorax in the flanks and on the abdomen the symmetry is less apparent On the shoulders it takes the shape of epaulets

In old cases the hypochromia forms a continuous surface which extends uninterruptedly to the whole shoulder and to the anterior side of the thorax and abdomen At times the skin on the trunk takes on a spotted appearance like the skin of a leopard due to areas of normal and pigmented skin

In the upper and lower extremities the lesions are similar and are situated in homologous regions There is vitiliginous achromia in the elbows and knees in the wrists and ankles in the planes of extension of the forearms and legs There is atrophoderma of the back of the hands and feet In the upper extremities the lesions are symmetrically disposed in the shoulders arms forearms and hands In the shoulders and arms the spots usually hypochromic are distributed in nummular areas separated by healthy skin This produces a mottled effect By growth the spots become confluent resulting in large hypochromic surfaces which extend uninterruptedly from shoulders to hands In some patients the macular process is limited to the surfaces of extension while in others the flexor surfaces are also affected In general achromia is total and vitiliginous in or slightly over or under the elbows Less frequently, the flexion and extension surfaces of arms forearms or of both are the sites of reticular leucomelanoderma or of diffuse leucoderma between which are areas of normal or pigmented skin

In some cases the extensor surfaces of arms or forearms or of both display pigmented erythroderma lead gray or slaty color slightly scaly or on

Dopa oxydase reaction demonstrates that pigmentation coincides with hyperplasia and hypertrophy of melanoblasts although at times a paradoxical state is observed in which there is notable diminution or absence of melanoblasts in a slaty spot with diminution or absence of epidermic melanin This is due to the fact that melanin which has been phagocytized by melanophores may remain stored in them for a long time while melanogenesis is exhausted or remains active only in a few isolated melanoblasts In highly pigmented lesions the dermis is transformed into a reservoir of melanin

The pathologic histology of the initial lesions and pintids is similar Epidermis shows parakeratosis acanthosis intercellular edema which sometimes gives rise to microscopic vesicles and migration of leucocytes through the

Fig 16—Histologic section of initial lesion in the papular phase Parakeratosis enlargement of the interpapillary cones migration of leucocytes across the epidermis Dense infiltration of the papillary structure and of subpapillary portion formed by lymphocytes plasma cells polymorphonuclear neutrophiles and histiocytes Intense edema and marked vascular proliferation

epidermis Cutis shows a dense inflammatory infiltration formed by lymphocytes plasmocytes polymorphonuclear leucocytes and histiocytes In some cases a more or less marked local eosinophilia is observed The inflammatory infiltration is principally perivascular although by confluence diffuse inflammatory infiltration of the entire superficial portion of the cutis may occur Frequently numerous melanophores filled with melanin are observed Exceptionally we see giant cells

The histologic aspect of the lesions of the later phase depends upon the clinical aspect of the lesion taken for biopsy In scaly and lichenoid lesions and in keratodermia there is predominance of parakeratosis hyperkeratosis

the lesion is a dirty gray or silver white color These are situated upon infiltrated cyanotic leucomelanodermic skin in which the creases are exaggerated Pilosebaceous follicles show follicular keratosis

In the feet the lesions are identical to those described in localized clinical forms

Some authors describe pigmentary spots in hairy skin as well as in the mucosa and semimucosa Hair in the diseased area may be normal or atrophic or it may present canities Canities is particularly constant when situated over leucodermic spots

In the nails, punctiform and striated leuconychia has been described but onychogryposis is more frequently observed

In localized as well as in generalized forms but more frequently in the latter the superficial glands show variable enlargement Glands in the axilla and groin may attain the size of a pigeon s egg

Some authors have described aortitis in a great number of patients We have never encountered it Lack of extensive necroscopic investigations prevents affirmation or denial of its presence

Pruritus has been reported by some authors and denied by others In our experience pruritus may be absent or mild or severe continuous or intermittent Scratching frequently produces excoriations with resultant wounds from which oozes serous fluid in which we have found treponemata

PATHOLOGY

All the cutaneous manifestations of pinta are the consequences of localization and multiplication of treponemata in the skin causing chronic superficial dermitis Pigmentation hyperkeratosis lichenization atrophoderma desquamation and all the cutaneous lesions described above are the early or later results of this superficial dermitis

Pintous dyschromia is the result of disturbance of the production and distribution of melanin secondary to a previous inflammation In the hypochromic or achromic spots there is decrease or total absence of cutaneous pigment with decrease or absence of melanoblasts as shown in the dopa oxydase reaction The rosy tint frequently seen in hypochromic and achromic spots is due to inflammatory erythema

Slate blue and lead gray areas and all shades of both are due to an increase in dermic and in smaller proportion epidermic melanin The larger the quantity of pigment in the dermis and the more superficial its localization the darker will be the coloration Weak lead gray color results from lesser quantity of melanin deposited in the dermis and a simultaneous decrease of epidermic melanin Simultaneous increase in epidermic and dermic melanin gives rise to areas with intense blue black color Increase in epidermic melanin without much participation of dermic melanin gives rise to spots of dark red tone the larger the quantity of melanin the darker these spots

The violet color of some areas is due to erythema superimposed on deep pigmentation

DIAGNOSIS

Diagnosis of pinta in the dyschromic phase is not difficult since there is scarcely any dermatosis for which it could be mistaken However, clinical forms localized in the hands and feet, particularly *frequent in countries where* pinta occurs sporadically are indistinguishable from *pintoid syndromes* caused by syphilis and yaws (León Blanco) This is due to the fact that at the pres*ent time there* is no laboratory method which specifically differentiates these three treponematoses

The initial lesions and pintids may be confused only with certain syphilodermas with some epidermomycoses and with clinical forms of cutaneous leprosy or in some cases with pityriasis rosea Laboratory methods permit easy *differentiation of pinta from these last affections* But to differentiate it from syphilis the greatest care must be exercised since all of the diagnostic laboratory methods are the same for pinta as for syphilis In some cases diagnosis can be carried out only after the most minute clinical and epidemiologic studies

The only laboratory methods useful in the diagnosis of pinta are the serologic reactions Kahn Wassermann Mazzini Meinicke etc and the search for treponemata in the cutaneous lesions

In the dyschromic phase serologic tests are positive in practically 100 per cent of the cases Every case which in this phase shows a negative serologic reaction should not be considered as pinta unless treponemata are found in the cutaneous lesions

In the primary period while the initial lesion is the only lesion serologic *reactions are almost constantly negative* *In the early phase* of the period of generalization reactions are positive in 70 per cent of the cases, the percentage increases as the development of the disease progresses

Examination for treponemata in cutaneous lesions and in glands may be carried out by silver impregnation of biopsy material, using the method of Jahnel Warthin Starry Dieterle * or a dark field examination may be made of serous matter obtained by puncture of the glands or by erosion and expression of cutaneous lesions This last method is the most rapid and the easiest *It is essentially as follows* *With a bistoury or curette a very* superficial abrasion is made in the skin of the suspected lesion *Pressure with a pair of* forceps is applied to express a few drops of serous matter from the lesion If the first drops contain many red blood cells they are discarded *until a clear* drop is obtained This drop is mounted on a slide covered with a cover glass and examined under the dark field microscope A smear may be made and stained with Giemsa stain or impregnated by the Krajian or Fontana Tribondeau methods

TREATMENT

In Mexico and Colombia from time immemorial people have used metallic mercury in the form of unguents or vapor for the treatment of pinta as well

*The editor (R B H G) prefers the Krajian method Chapter 70

and acanthosis, and the inflammatory infiltration of the cutis is intense Proliferation and dilatation of blood vessels is marked Elastic fibers are decreased or absent

In atrophic lesions the epidermal layer becomes thinner although at times isolated hyperkeratosis may be observed With disappearance of the inter papillary crests the dermoepidermic line of union is straight or slightly wavy, due to the fact that papillae are erased Elastic fibers are missing in the papillary portion of the dermis On the other hand a condensation of the elastic network may be observed in the deep portion In this type of lesion inflammatory infiltration is absent or at a minimum Frequently the atrophic lesions are achromic at the same time but this is not generally so on the other hand, some pigmentary spots are atrophic at the same time

Treponemata can be demonstrated in all cutaneous lesions by proper methods In the initial lesion and in pintids they are in the epidermis as well as in the dermis In lesions of the later phase we have succeeded in finding them only in the epidermis and in the epithelial portion of the piloseblaceous follicles

The histologic lesion found in the glands adjacent to the initial lesion consists of hyperplasia and hypertrophy of the follicles To this is added inflammatory reaction of the capsule and medulla characterized by presence of plasma cells and lymphocytoid cells Treponemata are encountered constantly

In glands in the later phase a marked inflammatory reaction is observed characterized by infiltration of the lymphoid tissue by plasma cells basophilic cells polymorphonuclear neutrophiles eosinophiles and proliferated fibroblasts This chronic adenitis leads to such marked sclerosis that the lymphoid tissue is reduced to a narrow subcapsular band which like a helmet surrounds the central sclerosed portion of the gland

Generally and constantly in those cases which present extensive dyschromia the affected glands show a bluish or violet color This color is due to the enormous quantity of melanin which accumulates in the glands

MODE OF TRANSMISSION

In 1860 J J Leon stated that pinta was transmitted from human being to human being by the bite of the gegen (gnat*) Since then most authors who have made extended studies of pinta believe that the disease is communicated through a vector possibly a hematophagous arthropod perhaps belonging to the genus Simulium Leon Blanco and Soberón Parra (1941) succeeded in transmitting the disease by using as a vector a fly of the genus Hippelates

The easy transmissibility of pinta from person to person favors the idea of its contagiousness and also the fact that some cutaneous lesions accidentally opened may be potentially infective (Leon Blanco) But the final decision concerning the mode of transmission still rests upon results of research to be carried out in the future

as bichloride of mercury in the form of lotions potions and pellets Physicians in these countries during the past century recognized the popular tradition and regulated the mercurial medication (León, 1862)

Since Gratz (1913) discovered the curative action of salvarsan in this disease arsphenamine and neoarsphenamine have been used Mercurials and bismuths should be used only if arsenicals cannot be administered Arsenicals cure pinta rapidly in relatively low dosage In pinta there is no reason for the intensive and prolonged treatment such as is used in syphilis

A total dose of 2 50 to 3 50 Gm of neoarsphenamine administered every five days in doses not to exceed 0 60 Gm cures any case of pinta definitively All cutaneous lesions are cured with the exception of leucodermic vitiliginous spots At times deep pigmentations (slaty spots) remain four to six months before they disappear This is due to the fact that reabsorption of melanin takes place slowly

Zozaya and Varela (1943) have used penicillin with as much success in pinta as in syphilis

In the dyschromic phase serologic reactions are irreducible even with the most intensive treatment In the primary period and in the early phase of the period of generalization reactions become negative some months after termination of the treatment

PROGNOSIS

Prognosis in pinta is excellent It does not seem to shorten life and cutaneous lesions are rapidly cured under treatment

With our present status of knowledge of the disease it cannot be stated with certainty that pinta causes visceral lesions such as the aortitis described by some authors It is not known whether the pathologic alterations in cerebrospinal fluid similar to those observed in syphilis and indicated in some cases from Cuba by Pardo Castello are caused by syphilis or by pinta

PROPHYLAXIS

1 The treatment of all patients should be obligatory

2 Contact between normal and diseased individuals should be prevented

3 Hygienic living conditions of inhabitants of pintogenous zones should be improved

ation with louse borne typhus and in some cases mixed infections of typhus and relapsing fever coexist (Robinson 1942) Apparently there is no reservoir host other than man in the louse borne relapsing fever for this reason the delousing of people and their clothing is an effective means of limiting the spread of the disease

Tick borne relapsing fever occurs usually sporadically Infected ticks transmit the spirochetes of relapsing fever by their bite to man Many species of soft ticks (Ornithodorus) are known to be naturally infected with relapsing fever spirochetes Of the species found in North and South America five species *O hermsi O parkeri, O rudis, O talaje,* and *O turicata* have been proved to be vectors of relapsing fever In Africa Asia and Europe the following species have been proved to transmit relapsing fever *O erraticus O moubata O savignyi O asperus O tartakovski O tholozani* and *O verrucosus*

Fig 107—Thin blood film showing spirochetes of relapsing fever Wright stain (×2700)

Inasmuch as the soft tick remains infected for life and passes the infection through its egg it would seem that Ornithodorus itself is the principal reservoir host of *Bor recurrentis,* although mammals such as monkeys chipmunks prairie dogs rats and squirrels may acquire the infection from ticks and serve as reservoirs for a shorter period

Crab lice *(Phthirus pubis)* and bedbugs *(Cimex lectularius)* apparently play no role in transmitting this disease

PATHOLOGY

Relapsing fever produces no pathognomonic morbid anatomy However the spirochetes may be demonstrated in the spleen brain and other organs

CHAPTER 12

RELAPSING FEVER

ARDZROONY A. PACKCHANIAN

DEFINITION

Relapsing fever is an acute infectious disease characterized by alternating febrile and afebrile periods. The disease is caused by specific spirochetes and transmitted to man by soft ticks (*Ornithodorus*) or by body lice (*Pediculus*).

ETIOLOGY

The etiologic agent of relapsing fever is a spirochete belonging to the genus Borrelia. Many species of this genus have been described as the causative agent of relapsing fever; these so-called species or strains include *Bor. duttoni*, *Bor. hispanica*, *Bor. kochi*, *Bor. novyi*, *Bor. obermeieri*, *Bor. recurrentis*, etc. At the present time it is not definitely known whether these so-called species or races are true separate taxonomic species or whether they merely represent strains or varieties of one or two species. Morphologically, all of the so-called species and strains are identical. Likewise the disease produced by the various "species" are similar clinically. These strains or variants differ from each other principally in their serologic characteristics. It is claimed that in a patient or in an animal any given strain of Borrelia assumes different serologic characteristics during each relapse.

The spirochetes which cause relapsing fever are cylindrical or slightly flattened, with pointed ends, and measure from 8 to 20 microns in length and from 0.2 to 0.3 microns in diameter. Each spirochete has about three to seven large wavy, irregular, inconstant spirals, each spiral having an amplitude of 1.5 microns. These microorganisms are highly motile and divide by transverse fragmentation. Borrelia stain readily with Wright, Giemsa, and other common bacteriologic stains. The spirochete of relapsing fever probably has never been successfully cultured in vitro. Because of their flexibility and small diameter, relapsing fever spirochetes can be passed through a thin-walled Berkefeld filter (Novy and Knapp, 1906).

EPIDEMIOLOGY

Both tick-borne and louse-borne relapsing fevers are widely distributed and found in most parts of the world. The louse-borne disease is found in cold as well as in warmer climates, while tick-borne relapsing fever occurs chiefly in warmer regions.

Louse-borne relapsing fever appears usually in the form of small or large outbreaks or epidemics, although occasionally sporadic cases are encountered. The infection apparently is not transmitted to man by the bite of the infected louse; however, if the louse is crushed and the material is rubbed into abraded skin, as by scratching, infection may take place. So far as is known, the spirochetes of relapsing fever do not pass through the louse egg.

Louse-borne epidemics are frequently associated with poverty, unhygienic conditions, and troop movements. The disease is often found in close associ-

DIAGNOSIS

During the febrile period the motile spirochetes with lashing movements may be demonstrated in a fresh wet preparation of the patient's blood by *dark field* examination preferably with a high power dry objective Stained thin or thick blood smears also are valuable for detection of the microorganisms in the blood The spirochetes of relapsing fever stain readily with Wright Giemsa and other common bacteriologic stains such as gentian violet and basic fuchsin When the central nervous system is involved the spirochetes can be *demonstrated at times in the cerebrospinal fluid*

Inoculation of laboratory rats (Rattus) with the patient's blood is also a valuable method of diagnosis About 5 to 10 c c of the patient's blood taken during the febrile period are placed in a sterile test tube containing a few glass beads and defibrinated by shaking Each of one or two rats is inoculated with 1 or 2 c c of the defibrinated blood The rat's blood should be examined for presence of spirochetes daily from the third to the twelfth day following inoculation as the disease is also a relapsing condition in rats Should it not be possible to inoculate an animal immediately the sample of defibrinated blood may be stored in the refrigerator for a period of several weeks and mice or rats inoculated when desired Defibrinated blood containing Borrelia stored in an icebox for two to three months still retains its power to infect susceptible test animals

Since Borreliae have never been cultured successfully in vitro cultural methods are valueless for diagnosis

Serologic tests are still in the experimental stage and at present are not practical for clinical diagnosis

PROGNOSIS

Relapsing fever is a self limited disease The mortality rate is probably less than 5 per cent but in certain outbreaks the mortality has been estimated at about 20 per cent The majority of cases that terminate fatally apparently are associated with debility malnutrition and other complicating conditions

TREATMENT

Since relapsing fever usually terminates spontaneously evaluation of specific treatment is difficult Although the ideal drug for treatment of relapsing fever remains to be discovered arsenical drugs are most commonly used *and should be given early in the pyrexial period* Detrimental effects have been reported when arsenicals are given immediately preceding the crisis The arsenicals when administered in an afebrile period, seemingly have no effect Some strains of *the spirochetes have a tendency* to become "arsenic fast through inadequate treatment Neoarsphenamine (Novarsenobillon) is given intravenously in a dose of 0 3 to 0 6 Gm for an adult and 0 01 Gm per kilogram of body weight for children One *injection is usually* adequate but injections may be repeated if necessary in two successive days and

Most of the fatal cases are due to complications as heart failure pneumonia or septicemia The spleen is nearly always enlarged and hyperemic and may be the site of microscopic miliary lesions Small capillary hemorrhages are often noted in the various tissues

CLINICAL PICTURE

The incubation period varies from about three to ten days After this fever makes its appearance quite abruptly the temperature rising to 103° to 104° F (39° to 40° C) or more within a few hours The onset may be accompanied by a chill or a chilly sensation Headache and muscular pains are almost constant symptoms and dizziness nausea and vomiting are noted frequently The pulse is increased proportionately to the temperature Slight jaundice is a common finding and in severe cases the icterus may become marked An erythematous eruption may be noted at times Delirium and signs of meningeal irritation may be observed on rare occasions The spleen is often palpable and the liver is usually tender After two to six days of fever the temperature falls to normal by crisis accompanied by profuse sweating

A relapse usually occurs after a three to ten day period which is afebrile and relatively asymptomatic The temperature rises almost as abruptly but seldom goes as high as in the initial attack The relapse as a rule does not last as long and the symptoms in general are not as severe as in the primary paroxysm A second relapse commonly follows an apyrexial period Not infrequently a patient has three or four relapses and in rare cases twelve or thirteen relapses have been reported

LABORATORY FINDINGS

During the febrile period albuminuria is usually present The leucocyte count is elevated to about 10 000 or 20 000 while there is fever The Wassermann reaction is said to be positive in a small percentage of cases

DIFFERENTIAL DIAGNOSIS

There are several febrile illnesses which at the onset must be differentiated from relapsing fever Malaria dengue and typhus would seem to deserve the greatest consideration as the disease progresses Finding *Bor recurrentis* in the patient s blood by direct microscopic examination or by animal inoculation establishes the diagnosis of relapsing fever The presence of Plasmodium in the blood smear indicates malaria A saddleback temperature curve bradycardia and leucopenia suggest dengue fever The similarity of the epidemiology of typhus and relapsing fever and their possible coexistence make their differentiation quite important The onset of typhus is less abrupt and in typhus the fever remains elevated for a longer period Relapsing fever does not give a positive OX 19 Weil Felix reaction although it is reported that the serum of relapsing fever patients agglutinates *Bacillus proteus* OX K (Zarafonetis et al 1946)

CHAPTER 13

LABORATORY DIAGNOSIS OF LEPTOSPIRAL DISEASES

A. Charlotte Ruys

INTRODUCTION

The first leptospiral disease to be recognized as such was Weil's disease. The etiologic agent of this disease was discovered in 1915 almost simultaneously by Inada and Ido in Japan and by Uhlenhuth and Fromme in France in a German military laboratory. The Japanese authors named it *Spirochaeta icterohaemorrhagiae*, the Germans *Spirochaeta icterogenes*. Noguchi (1918) suggested the generic name *Leptospira*. The generally accepted nomenclature at the present time is *Leptospira icterohaemorrhagiae*, priority being given to the Japanese authors. As early as 1916 in Japan Ido, Ito and Wani (1918) isolated another *Leptospira from a patient with seven day fever (nanukayami)* and recognized the organism as related to but not identical with the Leptospira of Weil's disease. Other leptospiras were soon found—*in* Sumatra in patients with relatively mild fevers with clinical pictures different from the typical Weil's disease (Vervoort 1922). During the course of the next twenty five years a number of leptospiras were isolated in Europe, Indonesia, Australia, Africa and India. These differed serologically but the various diseases which they caused resembled each other in their major symptoms although they were quite different epidemiologically.

In this chapter the identification of the leptospiras, the etiologic diagnosis of the disease and the value of the serologic differentiation will be discussed.

The most recent comprehensive surveys on these problems are those of Walch Sorgdrager and Bohlander (1939) and of van *Thiel (1948) to both of* which surveys several references will be made.

MORPHOLOGY

The genus Leptospira belongs *to the family of* Spirochaetaceae and is characterized by a flexible thread like structure consisting of a large number *of regular spiral coils. The amplitude of each coil* is approximately 0.5 micron. The length of the whole Leptospira varies under normal conditions between 8 and 12 microns. Degenerative forms may reach a length of 40 microns. The width is constant and approximately 0.25 micron.

The leptospiras multiply by transverse fission which may be followed under the microscope.

one "stimulation dose" from six to eight days after the second injection Oxophenarsine (Mapharsen) is administered intravenously in doses of 0 04 to 0 06 Gm

Recently, penicillin has been used in the treatment of relapsing fever, with seemingly good results however, the correct evaluation of this therapy and the optimal dosage will not be known until more cases are observed

In cases that fail to respond to arsenicals sodium or potassium bismuth tartrate given intramuscularly has been reported to be of value

Inasmuch as the spirochetes of relapsing fever are found in the brain and cerebrospinal fluid in rare cases and since neoarsphenamine and penicillin do not reach the cerebrospinal fluid in effective quantities relapses may be due to the persistence of the spirochetes in the central nervous system The use of the pentavalent arsenicals (as tryparsamide or Aldersone) may be of value but have not been given an adequate trial as yet

Symptomatic treatment and good nursing care assume great importance in the more severe cases

A strongly active Giemsa solution in tap water should be applied on the dried smear for 30 minutes at 37° C. Then the stain is renewed by a fresh Giemsa solution which is again applied for 30 minutes at 37° C. Victoria blue may also give good results. Great care must be taken to use clean slides and to wash away the stain very carefully by allowing the water to drip on the stain covered glass and rinsing the precipitate with the water. In well stained smears the color of the leptospiras is violet and the separate coils can be seen distinctly.

Leptospiras can be demonstrated in tissues by the Levaditi method.* Often they do not show the elementary spiral coils but they can be easily recognized.

At times a division into a number of micro leptospiras may be seen in films of old cultures. Gastinel and Mollinedo (1942) described in leptospiras granules with coiled filaments. They are invisible in the dark field; their nature is obscure.

FILTRABILITY

Leptospiras are able to pass through the pores of various filters. Their great flexibility, their extreme thinness and their actively boring movements permit them to pass through the pores.

NUTRITIONAL REQUIREMENTS

Growth requirements of leptospiras are not very complicated. They can be grown in a simple buffered peptone solution:

Peptone Wittet	0.1 per cent
Phosphate buffer pH 7.2	10 per cent
Distilled water	1 liter

Growth in this rather poor medium is, however, not very copious and often it is not even visible at all, so that for experimental and diagnostic work it is necessary to add some enrichment. Rabbit serum is widely used for this purpose, sometimes in combination with hemoglobin. One of the simplest media is that of Vervoort (1922), wherein growth is luxurious. Sometimes, however, the tap water is not suitable for cultivation.

Vervoort Medium

(Modified by Wolff and Schüffner)

Peptone Wittet	1 Gm
Ringer's solution	200 c.c.
Sørensen's phosphate buffer (pH 7.2)	100 c.c.
Tap water	1000 c.c.

Boil until the phosphates have been precipitated and filter after cooling. Distribute into small tubes. Sterilize at 100° C. The pH is 6.9 to 7.0.

Add 10 per cent sterile rabbit serum and inactivate at 56° C. for 30 minutes. Some rabbit sera agglutinate the leptospiras and cannot be used in the media, so that each rabbit serum must be previously tested.

*The editor (R. B. H. G.) refers the Levaditi method described in Chapter 0.
†Editor's note (O. F.): In America Difco or BBL peptones are used.

It is impossible to examine living leptospiras with the ordinary micro scope because the index of refraction is nearly the same as that of the sur rounding media (plasma urine culture fluid) Only with a dark field con denser can they be easily recognized

With a not too high magnification they look like strings of very closely packed small beads They have hooked ends and a rather rigid middle part and move only slowly through the field with rapid rotation on the longi tudinal axis When the medium is viscid they seem to have some traction and acquire some speed Then also the middle part may show its great flexi bility the movement becoming like that of a snake Sometimes the ends ex hibit a whipping motion

Great care must be taken not to mistake so called pseudoleptospiras for real ones Often thread like fibrin structures are expelled from the blood corpuscles in blood specimens These may show movements caused by cur rents in the liquid perhaps also by Brownian movement and may easily be mistaken for leptospiras

Fig 108 —Leptospiras stained with Giemsa solution after fixation with osmic acid vapor (×1500)

STAINING

Leptospiras cannot be easily stained They do not stain with simple dyes like gentian violet as the Borreliae do Gram s method is of no use for this purpose Good results can be obtained by staining with Giemsa solution The oldest method is that of Zuelzer who fixed the films with vapors of osmic acid and stained with Giemsa solution However Schuffner (1934) showed that the easiest method is to stain the films after drying without preliminary fixation With the usual fixatives the primary coils become invisible *

*The editor R. B H G prefers the Krajian method described in Chapter 70

to keep the cultures alive Incubation is mostly between 28° and 32° C To obtain rich cultures it is necessary to seed with large amounts of material For subculturing nearly one half of a cubic centimeter of the old culture is transplanted into the fresh medium

VIABILITY AND RESISTANCE

In cultures leptospiras may show a remarkable viability Cultures in Vervoort's medium kept *in the dark at room temperature without subculturing* sometimes remain alive for years Dinger (1932) demonstrated that in the *semisolid medium of Noguchi* a thick layer of leptospiras grows 10 to 12 mm below the surface and these organisms may remain fully virulent for years

Leptospiras are very sensitive to acid reactions They are killed very quickly in acid urine *To isolate them from urine it is advisable to alkalinize* the urine by keeping the patient on appropriate diet for some days before collecting the specimen They are not very sensitive to salts They may remain alive in sea water for several hours but they disappear more quickly from salt and brackish water than from fresh water (Ruys and Schüffner 1934)

They are killed at 50° to 55° C in 30 minutes They tolerate low temperatures well (Zuelzer, 1925) They can be kept alive in tissues for several months when frozen at -20° C In culture fluid at this temperature however they survive no more than five days They cannot be preserved by lyophilization (Stavitsky, 1945)

They have little resistance against the various disinfectants Bile kills them quickly They are not susceptible to sulfonamides Of the antibiotics penicillin is active it has been used successfully in animal experiments (Larson and Griffitts 1945 Borg Petersen and Rotwitt Schmidt 1945) Good results have been reported in a few patients

ANTIGENIC STRUCTURE

Soon after the discovery of leptospiras as the etiologic agent of various infections the question arose as to whether those strains which differ serologically are independent species or whether they are mere variants of the same species *This problem has not been solved to date and both theories* have their adherents The first strains recognized as differing from the classic Weil strains were *L hebdomadis, L akiyami* A in Japan, and *L pyrogenes* in Sumatra all of which cause an acute febrile disease but mostly without jaundice and with a much lower death rate than Weil s disease

When still more serolog cally *different stra ns had been isolated a more elaborate study* of the antigen c structure became necessary, especially since the various strains cause almost the same clinical *picture in man the d fferences be ng unimportant* and only in degree In addition the virulence for animals is not a reliable means of differentiation e ther

Antisera *from patients or sera prepared* by injection of cultures into rabbits agglutinate cultures of leptospiras often in a h gh titer

Because *of the very faint visib lity of the* leptospiras in ord nary light the agglutination is poorly visible macroscopically Pot (1936) reported that concentrated formal n killed

Another suitable medium is that of Korthof (1932), which is a slight modification of Vervoort's medium

Korthof Medium

Peptone Witte*	400 mg
NaCl	700 mg
$NaHCO_3$	10 mg
KCl	20 mg
$CaCl_2$	20 mg
KH_2PO_4	90 mg
$Na_2HPO_4 \cdot 2H_2O$	480 mg
Distilled water	500 c c

Heat the mixture for 20 minutes at 100° C cool and filter Sterilize at 100° C Then add 8 per cent of sterile fresh rabbit serum Tube the mixture and inactivate for one hour at 56° C

Noguchi (1918) prepared a semisolid medium in which growth is excellent but which is not suitable for agglutination experiments

Noguchi Medium

Rabbit serum	1 5 parts
Ringer s solution	4 5 parts
2% agar	1 0 part
Paraffin oil to cover the surface	

Noguchi used this medium also in combination with a fluid medium consisting of 1 5 parts of rabbit serum and 4 5 parts of Ringer s solution poured over the solid medium the whole covered with paraffin oil A drop of rabbit hemoglobin—1 part of defibrinated rabbit blood + 3 parts of distilled water—may be added to improve the results

Savino and Renella (1944) prepared a medium with several enrichment fluids

Savino Medium

KH_2PO_4	2 Gm
NaCl	3 Gm
MgSO	0 05 Gm
$CaCl_2$	0 01 Gm
Distilled water	1000 c c

Add as activator 0 1 per cent of yeast extract 0 5 per cent of caseine hydrolysate and 0 005 per cent of hematin

Adjust the reaction to pH 1 with HCl

Sterilize for 15 minutes at 115° C

Add 10 per cent sheep serum sterilized by filtration

Other media have been advocated—egg agar chorioallantoic membrane etc —but these have no advantages as compared with those described above which are simple to prepare and easy to handle the fluid media can be used in agglutination experiments

Leptospiras must be cultivated under aerobic conditions The optimum temperature for rapid growth is 37° C but lower temperatures are necessary

*Editor s note (O F) In America Difco or BBL peptones are used

is diluted with the *remaining culture fluid*, and it *might become too greatly diluted* if more strains were used. We have no absolutely monovalent sera such as we use in our bacteriologic serologic work.

Strains of the same species remove antibodies from a serum, strains of a related one only those belonging to the strain itself. The clear cut results obtained with this method allow of an exact identification. Several species are now recognized as serologic and biologic entities in which there is correlation with a distinct *epidemiologic behavior*.

However, strains considered to be of the same species may show minor serologic differences. Borg Petersen (1938), whose work was confirmed by Gispen and Schuffner (1939), demonstrated that the classical Weil strains fall into two groups, one complete with the antigens A and B, the other incomplete with only A. Both behave alike pathologically and epidemiologically, so that they may be considered as two biotypes of the same species. Probably the same relation exists between *rachmat*, incomplete, and *akiyami A*, complete biotype. Van Riel found the same relation between an Indonesian strain (Benjamin) and an African strain (Mukingilwa), neither of which has been fully tested with all other sera. According to van Riel, *L. canicola* also has the two types mentioned here. Table XII is a list of strains examined with agglutinin absorption tests.

TABLE XII

MICROORGANISM	PATHOGENIC FOR MAN	DISEASE	PRINCIPAL HOST	OTHER ANIMALS FOUND INFECTED
L. icterohaemorrhagiae (complete and incomplete biotype)	+	Weil's disease	R. norv. norvegicus	R. ratt. rattus, R. ratt. alexandrinus, dog, fox, horse, pig, sheep, Arvicola terrestris
L. canicola	+	Canicola fever	Dog	
L. grippotyphosa (*L. andaman B*)	+	Mud fever, harvest fever	M. arv. arvalis	Cl. glareolus, A. sylvaticus
L. bataviae (*L. mitis*, *L. oryzeti*)	+	Indonesian, Weil's disease, rice field fever	R. norv. norvegicus, Micromys minutus soricinus	R. ratt. brevicaudatus, cat, dog, R. ratt. diardi, A. sylvaticus
L. sarkoebing	+	?	A. sylvaticus, A. flavicollis	–
L. sejrø	+	Sejrø fever	Mus spicilegus, A. sylvaticus	–
L. pomona (*L. australis C*)	+	Swineherd's disease, leptospirosis, australis C	Pigs	Dog, R. norv. norvegicus
L. australis A (*L. ballico*)	+	Cane fever	R. ratt. culmorum	Dog, R. norv. norvegicus, R. ratt. rattus
L. hebdomadis	+	Seven day fever, nanukayami	M. montebelloi	*Dog*
L. pyrogenes (*L. salinem*, *L. australis B*)*	+	Spirochaetosis febrilis	?	R. ratt. brevicaudatus
L. autumnalis (*L. rachmat* incomplete, *L. akiyami A* complete)	+	Autumnalis fever, hasami, akiyami	R. ratt. brevicaudatus, A. speciosus	M. montebelloi
L. ballum	+	?	Mus musculus (white variety)	Mus spicilegus

*In agglutination tests these are the same; in absorption tests there are small differences.

cultures may show agglutination visible to the naked eye, but unfortunately with these antigens the titers are lower and a much greater quantity of cultures is needed

This method and others based on the same principle have found only few followers, so that the serologic tests must be controlled by the dark field examination Serum dilutions made with a buffer solution are mixed with equal quantities of a rich culture and kept at room temperature After two hours, the results can be read provisionally, but the titer is not determined until the next day

In the lower dilutions of a strongly active serum, agglutination is clearly visible, in the higher dilutions, lysis complicates the picture The conglomerates of agglutinated leptospiras begin to show signs of lysis, until, at the end, only shapeless balls can be found, and finally nothing is seen except a few freely floating single leptospiras The titer end point is the last dilution of the serum which shows some difference in number with the control

Attention must be called to the fact that sometimes "nests" of leptospiras grow in rich cultures These may resemble agglutinated leptospiras In the "nests," however, each leptospira is entire and actively moving, in agglutinated conglomerates, the leptospiras have a damaged appearance and the movements finally cease

To avoid the danger of working with living leptospiras and to be able to have a stock of antigen ready at hand, some laboratories use formalin killed cultures It is necessary to use chemically pure formalin and no more than 0 5 per cent Impurities may cause nonspecific acid agglutination (Zuelzer, 1932) When dead cultures are used however, the lysis is absent and agglutination becomes manifest in much higher dilutions than with living cultures, where this phenomenon has been obscured by the lysis The titer of the sera tested with killed antigens is on the whole somewhat lower than when the titer of lysis is determined with living ones (Walch Sorgdrager Schuffner, Bohlander, 1938) The results with these antigens are less specific than with living organisms The formalin antigens can be kept for a limited time only because clumping begins sooner or later, probably caused by formic acid originating from the formalin under the influence of light

Complement fixation tests have also been used in serologic work but they are less specific and have practically been abandoned To determine the antigenic structure of a strain, monovalent rabbit sera are used, which should have a titer of not less than 10,000 They agglutinate and lyse strains of the same species to the same titer or sometimes less, the lowest being one tenth of the titer

Other species may show a strong co reaction, but they never reach more than one third of the titer (Walch Sorgdrager 1938, Walch Sorgdrager and Bohlander, 1939)

Some species are serologically closely related (*L canicola L icterohaemorrhagiae*), others are independent (*L bataviae*) For an exact diagnosis, however, agglutinin absorption tests are necessary, especially in those cases where co reactions are strong The absorption test first described by Ruys and Schuffner (1934) and improved by Schuffner and Bolander (1939) is made as follows

Agglutinin Absorption Test

Use a well grown culture in Vervoort's medium, killed with 0 5 per cent formalin Centrifuge 100 c c of this culture for 20 minutes at 10,000 r p m

Pipette off the supernatant fluid

Mix the remaining 0 45 c c of concentrated culture with 0 05 c c of the serum diluted to a titer of 1 3,000

The antibodies are fixed within 4 hours, but the mixture can be left overnight at room temperature

Centrifuge at 10,000 r p m for 5 minutes, and use the supernatant fluid for agglutination tests Van Riel (1946) prefers to perform the absorption with living cultures

It is difficult to absorb a serum with many strains because a leptospira culture cannot be entirely deposited at the bottom of a tube, and some fluid remains in the tube The serum

demonstrate the leptospiras The culture is the most reliable method but it often gives positive results only after quite a long time (one and one half to four weeks) If the material is contaminated, the addition of 400 mg of a sulfonamide to the medium may give a pure culture of leptospiras (Stavitsky 1945)

To demonstrate the leptospiras by means of test animals young guinea pigs 150 to 200 Gm should be used preferably also young hamsters because these animals are sensitive to leptospiras (*L canicola*) which are only very slightly pathogenic for guinea pigs (Randall 1948)

The inoculation should be made into the peritoneal cavity with 0 5 c c of blood Daily examinations from the third day on may show leptospiras even in those cases in which the strain does not cause the animal to become sick If the animal develops fever the blood is usually positive and pure cultures may be obtained by inoculation of the blood obtained by puncture of the heart, into suitable media Guinea pigs dying of leptospirosis show hemorrhages and mostly a severe jaundice At autopsy the liver and kidneys sometimes contain leptospiras in abundance in other cases very few or none are found The adrenals are always positive

White mice are also used they are susceptible to many strains of leptospiras but one must bear in mind that white mice may also be spontaneously infected as first described by Bessemans and Thiry (1929) and later by Schuffner (not published) Ruys Mankenhof and Wolff (1948) found two colonies of white mice to be heavily infected with *L ballum* which were excreted in very large quantities One must be sure that the colony of mice in use is free from spontaneous infection Bessemans Thiry and Tiellin (1933) demonstrated that some strains of *L icterohaemorrhagiae* kill the mice quickly and that others cause practically no symptoms except a constant urinary excretion of leptospiras virulent for guinea pigs

Leptospiras in Urine

Leptospiras may appear in the urine from the beginning of the second week of the illness on Direct examination in the dark field sometimes shows the leptospiras in great numbers If the urine is acid most of them will be dead and will show the typical rigid appearance Passage through a susceptible animal (guinea pig hamster) is necessary to isolate them from the urine The patient should be given an alkalinizing diet a few days before the specimen is to be collected to prevent the damage of acid urine The simplest way to obtain a positive result is to take the second portion of urine of the day and to inoculate the animals intraperitoneally with one cubic centimeter of the freshly excreted urine at the bedside of the patient Urine sent to the laboratory seldom contains living leptospiras

Leptospiras in the Cerebrospinal Fluid

As early as 1916 Costa and Troisier described a case of Weil s disease in which the principal symptom was meningitis Since that time the involvement of the meninges as a constant and sometimes predominant symptom of leptospiral infection has become well known There is however, no correlation between the seriousness of the clinical symptoms and the pathologic changes or the presence of leptospiras in the spinal fluid

There are a number of other strains which have been more or less exhaustively examined *L bovis*, *L vituloreum*, *L icterohaemoglobinuriae L schüffneri L mukingilwa*, *L andaman* A, the strains H and H C Veldrat Semarang 173 Djasiman and many others Our knowledge of either the serology or the epidemiology of these organisms however, is still too incomplete to include in Table XII

Variability

So far as I know no variation in serologic behavior has ever been observed The old strains from the Amsterdam collection have all remained stable No conclusive animal experiments have ever shown a transition of one type into another The experiments of Uhlenhuth and Zuelzer (1922) and of Baermann and Zuelzer (1923) who considered the various strains to be all variants of one classical species are open to criticism

Van Riel (1946) however basing his conclusions on his experiments in Africa with a number of strains but not with all types now available defends the thesis that intermediate types exist and that there are transitions from one type to another He emphasizes that strains which belong serologically to *L grippotyphosa* in Central Africa cause a disease with frequent jaundice and a high death rate However as long as no exhaustive study of the epidemiology has been made the picture is not complete and conclusions are premature

DEMONSTRATION AND ISOLATION OF LEPTOSPIRAS

In all leptospiral infections the microorganisms circulate in the blood during the first week of the illness After the first ten days positive blood cultures are very rare Bone marrow has been found positive even on the twentieth day (Dreyfus and Montefiore 1939) In the latter phases of the disease the leptospiras may be excreted with the urine Sometimes the spinal fluid contains leptospiras in incipient stages At autopsy both the liver and the kidneys may contain leptospiras

Leptospiras in the Blood

Blood films stained with Giemsa stain very rarely show leptospiras Ordinary dark field examination of blood also rarely gives a positive result and many so called positive findings have been caused by pseudoleptospiras mistaken for actual leptospiras With the centrifugal method however leptospiras may be demonstrated in the blood in some cases during the first days of the illness (Ruys 1933)

For this purpose one part of a 1 per cent sodium oxalate solution in phosphate buffer pH 8 1 is mixed with 9 parts of blood The mixture is then centrifuged for 15 minutes at 1500 r p m The clear plasma is examined under the dark field microscope with low magnification If no leptospiras are found the remainder of the plasma is centrifuged for 20 minutes at 10 000 r p m The sediment may show the leptospiras Blood collected in Liquoid Roche (15 to 20 c c blood in 4 c c of a 1 per cent polyanethol sodium sulfonic acid solution in saline = Liquoid) can be used also for dark field examination after the first centrifugation and sediment can be obtained from the plasma (van Thiel 1948)

It is unfortunate that this rapid method which permits an early diagnosis within half an hour after the sample has been taken is not absolutely reliable In several cases microscopically negative blood specimens yielded positive cultures or animal inoculations On the other hand no other method gives so quick an answer so early in the disease All three methods should be used to

Strong co reactions are however often observed and in these cases absorption tests are indicated (see also Ruys Minkenhof and Wolff 1948) Sera of patients infected with the incomplete biotype of *L icterohaemorrhagiae* may show titers against *L canicola* which are as high as and at certain moments even higher than against the causative strain This nonspecific titer rises more quickly and disappears *sooner than the specific one* so that in convalescence the titer against the causative strain is always the highest Even a rising titer against a certain strain in itself however is no proof that this strain is the etiologic one

The absorption test gives immediate and more reliable information

A titer below 1 1000 may indicate that the causative species was not included in the series of strains used for the tests it may be only a co reaction In convalescence the titer drops but the serum may react positively for years after the illness be it only in low dilutions (1 30 to 1 300)

In Sumatra Wolff (1936) found the reaction negative one year after the disease in most cases Low titers always indicate further careful examination

Patients who have been treated with immune serum at the beginning of the disease form antibodies only very slowly and high titers are not reached at all (Schuffner 1942) The serologic diagnosis can be conclusive only if all sources of error have been considered and excluded

Antibodies in Urine

In addition to the antibodies in the blood the urine also may contain specific agglutinins and lysins (van der Hoeden 1936) Formalinized cultures should be used for nonsterile urines The concentration of antibodies has no relation to the presence of albumin in the urine The titer of the urine is lower than that of the blood In a few cases it was only 1 2 but it may rise to 1 256 Co reactions are much rarer with urine than with sera

Antibodies in Spinal Fluid

In some cases of leptospira infections the spinal fluid contains antibodies but seldom in larger quantities Walch Sorgdrager (1938) found that undiluted spinal fluid was never positive in eleven patients with Weil s disease with and without meningeal symptoms Gsell (1946) however, mentions positive results in low titers from the second week of the illness on especially in cases with serous meningitis The titer varies between 1 2 and 1 100 and sometimes it is even higher than 1 100 A titer of 1 10 is considered proof of the infection

GENERAL REMARKS

The various methods outlined above make an etiologic diagnosis possible either by isolating the causative agent or by serologic examination A refined serologic technic is often required The question has often been raised

In all cases of Weil s disease or canicola fever in Amsterdam Minkenhof could demonstrate a serous meningitis in the second week while in only a few cases was the number of cells high Gsell and Rimpau (1944) stress that in the various leptospiral forms of meningitis during the first days of the illness no inflammatory changes can be observed despite distinct meningeal symp toms They always appear in the second and third weeks however Only rarely can the leptospiras be isolated from the spinal fluid Schuffner and Walch Sorgdrager (1936) found them only in one out of twenty five cases of Weil s disease with meningeal symptoms Cultures and animal inoculations are indicated when it is necessary to examine spinal fluid

Leptospiras in Post Mortem Material

The demonstration of leptospiras at autopsy may be possible by dark field examination of smears from the liver kidneys or adrenals In tissues the silver impregnation by the Levaditi method* will show the leptospiras in these organs Cultures will be possible only immediately after death In all other cases animal passage is necessary In chronic animal carriers (rats dogs mice but not rabbits or man) the process in the kidneys is sharply lo calized to limited parts of the cortical substance leptospiras will be found in layers on the epithelium of the convoluted tubules Several parts must be examined before a diagnosis of leptospiral infection can be excluded (Schuff ner and Kuenen 1923)

Leptospiras in Surface Water

Surface water is often the source of infection with leptospiras (Weil s disease mud fever) but it is very difficult to demonstrate these microor ganisms in the water Microscopically they cannot be distinguished from the nonpathogenic *L biflexa* which is often found in water

The only reliable method to date is that of van Thiel and co workers who bring the warmed water (37° C) into immediate contact with the tissues of susceptible animals either by bathing guinea pigs with an abraded skin in the suspected water or by letting this water flow through the subcutaneous tissue of the animal By this method even very small numbers of pathogenic lepto spiras can be isolated from the water

SEROLOGIC DIAGNOSIS

If no leptospiras have been isolated from the patient the diagnosis can be made serologically in a number of cases The antibodies do not usually appear before the seventh to tenth day of the illness They then increase rapidly and reach the highest titer in the third or fourth week The reliability of this method depends to a great extent however on the number of strains with which the serum is tested

If there are no co reactions and the titer has risen to 1 1000 or more during the course of the illness the probable cause of the disease may be established in this way

*The editor (R. B H. G) prefers the Krajian method as outlined in Chapter 70

As long as the epidemiology of the various types or species has not been sufficiently clarified we think it necessary to keep them separated even though only provisionally for some

whether it is necessary to go so far in serologic differentiation and whether the diagnosis of a leptospiral disease without further differentiation would not be enough

A typical case of Weil's disease may be recognized as such by its sudden onset high fever, conjunctival injection muscular pains jaundice albuminuria and meningeal symptoms The death rate is high However the mistake of Noguchi's co workers who mistook cases of Weil's disease for yellow fever, is too well known

Since more attention has been paid to the frequent occurrence of less typical cases we know that practically all leptospiral infections produce in principal the same clinical picture

In infections with some strains jaundice is frequent (Weil s disease *L bovis)*, with other ones it is rare *(L canicola, L grippotyphosa)* other groups are intermediate Serous meningitis is a predominant feature in some *(L canicola L pomona)*, in others it is not often described The renal and extra renal disturbances which influence the production and composition of the urine (Klarenbeck and Schuffner 1933) may be severe *(L icterohaemorrhagiae, L bovis L icterohaemoglobinuriae)* or practically absent *(L canicola, L grippotyphosa)* On the whole the differences are in degree never essential The pathogenicity of the various types or species for experimental animals is not the same but this quality is not essential either Thus far the only reason but a very important one why differentiation seems indicated is the difference in epidemiology The serologically different strains often show a quite distinct parasite host relationship and hence a typical epidemiologic behavior (see also Table XII)

L icterohaemorrhagiae lives in the kidneys of the rat *(Rattus norvegicus norvegicus Rattus rattus alexandrinus)* where it may persist for the whole of the lifetime of the animal *L grippotyphosa* is found in the kidneys of the vole but after a longer or shorter period the animal may be free of it (Schuffner and Bohlander 1943) *L canicola* is found only in the dog as a carrier *L pomona* in Switzerland is found in infections of swine (Gsell 1946) *L hebdomadis* is confined to *Microtus montebelloi* in Japan and to dogs in Medan

Sometimes it is difficult to decide whether finding a certain animal as a leptospira carrier is mere chance or whether it means that this is the real animal host and the reservoir which enables the parasite to persist During the last years several diseases have been recognized as leptospiral infections for example swineherd s disease in Switzerland *(L pomona)* jaundice in Palestine *(L bovis)* a part of the cases with serous meningitis *(L canicola, L pomona L sejro L grippotyphosa)*, and many diseases in the Belgian Congo and Australia Several animals have been found to be carriers It will take some time and much work before we know how far minor differences in serology are accompanied by distinct epidemiologic behavior

The complete and incomplete biotypes seem to behave practically alike in all respects and therefore all groups are considered to belong to the same species

CHAPTER 14

WEIL'S DISEASE

ARDZROONY A. PACKCHANIAN

DEFINITION

Weil's disease or leptospirosis is an infectious disease caused by *Leptospira icterohaemorrhagiae* and characterized by sudden onset of fever, headache, nausea, vomiting, muscular pain, jaundice and hemorrhagic tendencies. Weil's disease is not to be confused with catarrhal jaundice or epidemic infectious hepatitis, for which a virus etiology has been suggested.

ETIOLOGY

The causative agent of the disease is a finely coiled spirochete which is now universally known as *Leptospira icterohaemorrhagiae* (Inada et al., 1916). See Chapter 13.

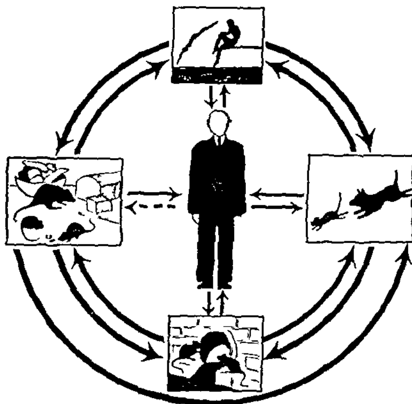
EPIDEMIOLOGY

Leptospirosis is world wide in distribution, occurring usually sporadically, but occasionally in small or larger outbreaks.

Wild rats (*Rattus norvegicus, Rattus rattus alexandrinus* and *R. rattus rattus*) are the chief reservoir hosts of *L. icterohaemorrhagiae*. Once these rats become infected, they serve as carriers of leptospiras throughout their lives, eliminating the microorganisms in the urine. This contaminated urine serves as the principal source of human infection. Dogs and mice (*Mus musculus*) have been found to be infected with typical *L. icterohaemorrhagiae* and may serve as a source of human infection (Packchanian, 1938). The leptospiras gain access to the body through mucous membranes or abrasions of the skin which have come in contact with water or other substances contaminated by the excreta of infected animals. Occupations that place people in environments habituated by rats and that are conducive to skin abrasions are associated with a strikingly higher incidence of Weil's disease. Miners, fish cutters, and employees of breweries, sewage disposal plants, garbage disposal plants, abattoirs and wharves most commonly contract the disease (Packchanian, 1941; Stiles and Sawyer, 1942).

PATHOLOGY

The most striking gross pathologic findings are hemorrhages and jaundice. Large hemorrhages are commonly found in the subcutaneous tissues, the viscera, pleura, or peritoneum, small or focal hemorrhages are found in almost all tissues. The liver and kidneys are generally enlarged to a moderate degree.



Microscopically, the liver shows changes varying from cloudy swelling to focal necrosis. Minute hemorrhages, disruption of the liver cell cords and

ment may be revealed by oliguria or anuria and azotemia The more severe cases present a *hepatorenal syndrome* and a typical uremic state may be the final picture in the fatal cases

WEIL'S DISEASE

(ICTEROHAEMORRHAGIC LEPTOSPIROSIS)

the cycle of infection

Fig 110—Cycle of infection in Weil's disease (icterohaemorrhagic leptospirosis)

LABORATORY FINDINGS

In the clinical cases of Weil's disease there is usually a leucocytosis of 10 000 to 20 000 or more with a moderate increase in the polymorphonuclear leucocytes Albuminuria is a rather constant finding and a microscopic *hematuria is frequently noted Nitrogen retention is evidenced by* an increase in the nonprotein nitrogen and blood urea nitrogen The icterus index is elevated at times to about 300 A biphasic van den Bergh reaction is typical but not constant The urine *shows an increased concentration of urobilin* and has been shown to contain bile late in the illness

dilatation of the sinusoids are also commonly seen The kidneys present de generation and necrosis of the epithelial cells of the tubules lymphocytic in filtration and small hemorrhagic foci in the stroma If the necropsy is per formed soon after death before post mortem changes have taken place and tissue sections are made and stained by the silver stain of Levaditi or Warthin * one may find large numbers of leptospiras in the intercellular spaces especially of the kidneys and liver

SIGNS AND SYMPTOMS

After an incubation period of seven to fourteen days the disease is com monly ushered in abruptly with a chill and pyrexia of 102° to 104° F (39° to 40° C) with headache and prostration Nausea and vomiting are fre quently present and general muscular pain is characteristic Petechial hem orrhages are sometimes observed in the skin conjunctivae and oral mucosa

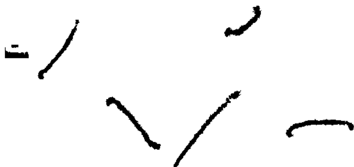

Fig 109 —*Leptospira icterohaemorrhagiae* from a culture Dark field illumination (Approxi mately ×4500)

There may be epistaxis hemoptysis and hematemesis in the more severe cases Conjunctivitis and photophobia are not infrequent findings Hiccup is often a persistent and an annoying symptom Delirium and signs of meningeal ir ritation are sometimes prominent features In most cases jaundice develops on the third to fifth day after the onset The intensity of the icterus and other symptoms varies greatly with the severity of the illness and probably many cases present very little or no jaundice at all In the milder cases the fever terminates soon after the jaundice appears In the more severe cases there may be a period of normal temperature followed by a secondary rise or the temperature may remain elevated for ten to twelve days The liver becomes large and tender the spleen usually is not palpable Renal impair

*The editor (R B H G) prefers the Krajian stain Chapter 70

from catarrhal jaundice and yellow fever was quite difficult, and some incorrect diagnoses have been made. For a summary of the differential diagnosis of these three diseases see Table XIII.

TABLE XIII. DIFFERENTIAL FINDINGS OF YELLOW FEVER, WEIL'S DISEASE AND INFECTIOUS HEPATITIS

	YELLOW FEVER	WEIL'S DISEASE	INFECTIOUS HEPATITIS
Etiology	Virus	Leptospira	Virus
Transmission	Bite of mosquito	Usually through skin abrasion	Contact (droplet and water)
Reservoir host	Man, wild animals	Rats (Rattus)	Man
Geographic distribution	Africa, South America	World wide	World wide
Person [illegible]	[illegible]	[illegible]	[illegible]
Occupa[illegible]	[illegible]	[illegible] sions	[illegible]
Occurrence (Morbidity)	Small or large epidemics	Sporadic	Sporadic and large or small outbreaks
Mortality	Usually high	Probably less than 5%	Probably less than 0.1%
Nature of pain	Severe muscular pain	Generalized muscular pain	Slight epigastric pain
White blood cell count	Decreased	Increased	Not changed
Culture test		+	−
Inoculation of Mus musculus	+	Carrier	
Inoculation of deer mice *(Peromyscus maniculatus gambeli)*	+	++	Not susceptible
Guinea pig	+	+	Not susceptible
Agglutination test with leptospira		+	
Mouse protection test *against yellow fever* virus	+	−	−
Post mortem findings	Hepatic necrosis	Leptospiras in kidneys, liver	Catarrhal inflammation of liver

PROGNOSIS

The mortality rate in Weil's disease is rather low. Although some workers report figures as high as 30 per cent, these statistics are based mostly on hospital admissions, which include only the more severe cases. Considering cases of all degrees of severity, the mortality rate is probably less than 5 per cent. Convalescence is likely to be prolonged.

TREATMENT

Although many drugs (arsenicals, bismuth, antimonials and sulfonamides) and antibiotics (penicillin and streptomycin) have been tried, there is no specific chemotherapy for Weil's disease at the present time. A commercial polyvalent antiserum is available and has been used with some good

DIAGNOSIS

Since there are other clinical entities which may give a similar clinic[al] picture, the absolute diagnosis of Weil's disease can be established only b[y] specific laboratory methods These consist of (1) direct microscopic dem[onstration] of *L icterohaemorrhagiae* in the blood or urine, (2) guinea pig o[r]

CHAPTER 15

FEVERS DUE TO RATBITE (INCLUDING SODOKU)

ARTURO CURBELO HERNANDEZ

In addition to the trauma caused by the common or laboratory rat, there often follows infection with specific bacteria introduced through the bite Two of these have been described *sodoku disease and Haverhill fever* These two forms are clinically similar, although the causative agents described in each are entirely different Sodoku and ratbite disease were formerly considered synonymous, but later studies and improved technical bacteriologic methods have changed the older concept by *defining Haverhill fever as a separate entity*

Sodoku is caused by a spirillum *(Spirillum minus)*, while Haverhill fever is due to a pleomorphic bacillus *(Streptobacillus moniliformis)*

HISTORY

That disease may follow a ratbite has probably been known since ancient times (Francis 1932a), although references to it are from a relatively recent period The first clinical work is that of Ives in 1831 and of Wilcox in 1839 It was not until about 1900 that Miyake (1900) gave a reliable description of ratbite fever as a clinical entity Later, Ogata (1908) referred to this same entity but introduced into the nomenclature the word "sodoku," the Japanese name for the disease Then descriptions and references by other authors appeared (von Ofenheim, *1909, Shikami, Horder, Middleton, 1910, Proescher and* Hata, 1912), outlining the clinical features of the disease, now differentiated with relative ease from other entities and undoubtedly due to a true bacterial infection Hata (1912) recommended treatment with arsenicals because of its resemblance to syphilis Today this treatment is used for the spirillary form, sodoku

Recently, numerous investigations have been carried out by different authors to demonstrate the cause of the disease, in this way numerous microorganisms have been isolated from the few cases studied *Staphylococcus aureus* (Miyake), *Neosporidium, Sporozoa muris* (Ogata), the *Micrococcus tetragena* (van Ofenheim), a *Telosporidium* (Shikami), and *Bacillus septicomuris* (Proescher) Some of these authors successfully inoculated laboratory animals, especially guinea pigs, but in general the investigations were not sufficiently conclusive nor was *the identity of the causative agent proved*

Bacteriologic investigations began to bear fruit with the classical report of Schottmuller (1914), who isolated a Streptothrix He called this *Streptothrix muris ratti* This investigator also reported a similar organism *(Streptothrix teraxerus cepapi)* from a second case, in a patient bitten by an African squirrel *(Teraxerus cepapi)* This investigation marks the beginning of bacteriologic progress in the study of ratbite fever

In 1916 a curious event occurred, in two consecutive numbers of the same medical journal two studies appeared on the etiologic factor of the disease One of these, by Blake (1916), appearing in the January issue, established the relationship of *S muris ratti* previously described by Schottmuller, to the disease, the other study by Futaki, Takaki, Taniguchi, and Osumi (1916), in the February issue, reported a new spirillary organism later called *Spirochaeta morsus muris*

The author wishes to express his gratitude to Dr A Anido Dr A Hernández Dr F Rio Leon and Dr D Velasco *of Santa Clara Cuba for* data included in this chapter

results, however, an insufficient number of human cases have been so treated for a correct evaluation of the serum Convalescent serum if obtainable, is probably of some value

The symptomatic treatment is the primary concern Maintenance of the fluid electrolyte balance is of utmost importance When the patient is able to retain food a high protein high carbohydrate diet with vitamin supplements is recommended Recently methionine has been used in cases of Weil's disease on the assumption that this compound protects the liver from damage

blood and are demonstrable in all cases if a diligent search is made As the process advances, other symptoms are found which are characteristic of this infection, such as falling out of hair in the ocular region associated with intense keratoconjunctivitis. Ulceration of the skin may also occur At the end of the fifth week the animal dies, spirilla are demonstrable in the blood in the lymph glands, spleen, kidneys, adrenals, and even in subcutaneous tissue

Intraperitoneal inoculation in the mouse does not produce the same picture as in the guinea pig Practically no clinical manifestations are produced, even after one or two weeks, the period of incubation in the guinea pig *Spirilla* appear in the blood, at first scanty, then in greater numbers The presence of organisms in the circulation of the mouse is maintained for a long time, but the animal does not succumb to infection The rat reacts in the same way as the mouse, although the mouse is preferred for demonstration of the microorganisms in the blood

Other rodents are also susceptible For practical purposes the guinea pig is the animal of choice Monkeys and rabbits also may be used

Fig 112 —*Spirillum minus* *A* to *F*, from lymphatic gland of human patient. Flagella can be easily seen *G* to *I* from blood of a guinea pig *A* to *F*, Giemsa stain, *G* to *I*, Fontana stain

Transmission.—The permanent reservoir of the organism is the rat and perhaps other Muridae which infect each other probably by bite or by ingestion of cadavers of those of the colony that have died and have been devoured by the others Conjunctival fluid may act as a transmitting medium as well as the ectoparasites so common in these animals

The bite of other animals (dog, cat, hutia, etc) may be infectious if the animal has been bitten by a rat, but these other animals may serve as occasional reservoirs of the disease Transmission by this means is exceptional

Transmission may occur by mouth, although this is rare This type of transmission was demonstrated (Laroderie) in a case of a soldier in World War I, in 1914, who ate a rat on a bet (Nevot, 1935)

Thus we have seen that transmission of sodoku may occur by animal inoculation and in various other ways, but these are exceptional in comparison with the natural manner, which is through ratbite

This spiral shaped organism which was described by the Japanese investigators became known more generally as *Spirillum minus*, according to Robertson (1924), who identified it as the species described by Carter in 1887 as the first spirochete isolated from rodents. Its taxonomic position has not been determined as yet, due to difficulties in the cultivation of this organism (Bergey, Breed, Murray, and Parker Hitchens, 1939)

Concerning the bacillary agent the facts are more definite. The *S muris ratti* of Schottmuller, confirmed by Blake also in a case of ratbite fever, has been observed by other investigators under different conditions. Tunnicliff isolated this microorganism from the lungs of rats with bronchopneumonia (1916a). Litterer (1917) used the term "Streptobacillus" for the first time in cases of ratbite fever in human beings. Dick and Tunnicliff (1918) found it in a case of weasel bite, Jones (1922) from the lungs of rats with pneumonia. Levaditi, Nicolaou, and Poincloux (1925) isolated *Streptobacillus moniliformis* from a clinical case not due to ratbite (erythema multiforme), without associating it with the Streptothrix of Schottmuller. This was undoubtedly the same organism. It was also isolated by Lemierre et al (1937) and others from the blood in a typical case of ratbite fever, thus reaffirming the fact that *S moniliformis* is a causative factor for the disease.

In 1926, Place, Sutton, and Willmer reported an epidemic in Haverhill, Mass. They isolated from the patients' blood and joints a microorganism for which they created a new genus which they called *Haverhillia multiformis*. The epidemic resulted from the use of unpasteurized milk. Later, this organism and this disease were apparently associated with ratbite (Dodd, 1926, Hazard and Goodkin, 1932, Scharles and Seastone, 1934). This led to the conclusion that the three microorganisms described under different circumstances in different countries and in different languages were identical (Brown and Nunemaker, 1942)

The suggestion made by Brown and Nunemaker to keep the name *Streptobacillus moniliformis* appears to be most pertinent, and the greater part of the most recent investigations have utilized this designation.

INFECTION BY SPIRILLUM MINUS (SODOKU)

Spirillum Minus Carter

Synonyms.—The bacterium has been described as *Spirochaeta morsus muris*, *Spirillum minus*, *Spirochaeta muris*, *Spirochaeta laverani*, and *Spirochaeta petit*. The first two terms are frequently found in the literature, the majority of authors preferring the term *Spirillum minus* Carter.

Morphology.—The organism is a short thick spirillum, measuring from 2 to 5 microns in length. It has pointed extremities, with one or more frequent and readily demonstrable flagella. The spirals are short and clearly visible in well made preparations. They are 1 micron in length and are rigid and regular. They are very motile, in this respect resembling vibrios.

Staining Characteristics.—The microorganism stains well with aniline dyes, and also with the usual blood stains. This facilitates their study in the blood, lymph, etc.*

Culture.—*S minus* has not been successfully cultivated in ordinary media. Observations must be made of the tissues of infected human subjects or inoculated animals.

Experimental Pathogenic Action.—It is very difficult to demonstrate this organism in man. Use of animal inoculation is preferable for diagnostic purposes.

From the experimental point of view, the guinea pig is the animal of choice in the study of sodoku disease, and the preferred routes of inoculation are cutaneous (scrotal), subcutaneous, and intraperitoneal. When inoculated with material from the patient (blood or lymph from a lesion or regional gland fluid), after an incubation period of one to two weeks, the guinea pig develops fever accompanied by glandular enlargement and marked reaction of the subcutaneous tissue of the anogenital region, especially apparent in the scrotum and prepuce of the male and the labia of the female. Spirilla appear in the

*The Krajian stain is recommended by the editor (R B H G)

CLINICAL PICTURE

There is rapid healing of the wound unless secondary infection interrupts the process This rarely occurs since physicians as a rule treat the wound locally *with antiseptics or antibiotics* Such local treatment however is useless in spirillary infections because these infections are too deep seated for the antibiotics to reach them If prophylactic treatment is desired at this point it is necessary to cauterize as deeply as the limits of the toothmarks of the animal In this way the development of sodoku may be prevented

The period of *incubation from the time the bite is inflicted until the* appearance of the first symptoms is variable averaging fourteen to fifteen days Periods as short as forty eight to seventy two hours have been cited and also long periods of about thirty days In one case the development of the local lesion from the time of the bite to the appearance of the first symptoms was just twenty four hours (Anido Hernandez Rio Leon and Velasco)

SYMPTOMATOLOGY

The disease begins suddenly History of a bite should immediately suggest the possibility of this disease At times the prodromal symptoms occur at the site of the bite mild edema reddening infiltration paresthesia the last however is not constant The symptoms may be divided into the fundamental groups (1) local symptoms and (2) general symptoms

Local Symptoms

Local symptoms are divided into two groups those which occur precisely at the site of the bite and those which affect the tissue next to the bite

Soon after the bite pain begins at the site of the bite followed by swelling and reddening with the formation of an *inflammatory nodule* *Edema develops* around the lesion which extends to neighboring tissue According to the intensity of this edematous infiltration the nodule takes on various colors terminating in ulceration due to focal necrosis A zone of lymphangitis is produced around the lesion

From this point spread more or less nodulated strands of lymphangitis which extend throughout the tissues of the region The regional glands are infiltrated and very painful and are accompanied by an inflammatory periadenitis Suppuration rarely occurs *Adenitis* is *sometimes so discrete* that it is very difficult to find it

General Symptoms

General symptoms may be considered as of five groups (1) fever (2) *exanthem* (3) nervous manifestations (4) pain (5) symptoms in other organs

Fever—Fever begins suddenly, as high as 40° C or more although in some cases it may be moderate with slow elevation Frequent chills occur with each thermic elevation This *febrile period averages three* to four days in duration followed by a second apyretic phase which may last about five days

PATHOLOGY

At the site of the bite, there occurs an area of intense cellular infiltration edema and marked degeneration leading to necrosis Fibrous production involves the different structures and connective tissue leading to sclerosis

Kaneko and Okuda (1917) described the following lesions renal congestion and epithelial degeneration of the tubules fatty degeneration of the liver

Fig 113 —Sodoku Chancre of inoculation Necrosis can be seen

Fig 114 —Sodoku Chancre of inoculation Heavy infiltration of tissue around the site of the bite

with central lobular necrosis with hyperemia and isolated hemorrhages congestion of lymphatic glands with interstitial hemorrhage diffuse pulmonary congestion intense medullary hyperplastic reaction hyperemia meningeal edema and desquamation of the bladder epithelia Spirilla can be observed in the lesions principally in the adrenals and in the liver

Lesions found in guinea pigs which have died of sodoku are on the whole, similar to those described in man without the special characteristics which may prove of some value in diagnosis

As to the cardiovascular apparatus aside from the tachycardia which accompanies the fever the majority of the patients show a marked lowering *of blood pressure*

There are definite blood changes There is almost constantly a certain degree of anemia this may be marked with a decrease in the hemoglobin The red count also decreases Rarely is there an increase in the number of red cells

Leucocytosis occurs although not high fluctuating usually between 10 000 and 20 000 although in some cases it may be as high as 40 000 This occurs in the febrile periods In afebrile periods the leucocyte count drops markedly sometimes as low as 4 000 In these cases with the return of the febrile period the leucocyte count rises again This is a fairly regular observation

The differential count shows changes that are especially noteworthy first there is an increase of neutrophilic leucocytes with a normal number of mononuclears An outstanding observation is the eosinophilia which may be *rather high Variations of these counts may be due to other conditions which* may be present in some cases

As to serologic reactions currently used in the diagnosis of syphilis (Wassermann Kahn Meinicke) the authors disagree However a positive reaction in the absence of syphilis may aid the diagnosis since it is possible to accept the theory of certain antigenic affinities among spirillary micro organisms

In the serum of these patients there may appear spirochetolytic sub*stances demonstrable by the Pfeiffer phenomenon*

COURSE

The disease shows various phases of activity each one progressively less intense It may last for weeks or months exceptionally even longer

In general the disease except in particularly serious cases tends toward recovery However this development may be hastened by adequate treatment as soon as diagnosis has been established When diagnosis is in doubt the disease may run its *full course a rare occurrence at the present time*

LABORATORY DIAGNOSIS

Laboratory investigations consist of the following

(1) Test for Presence of the Spirillum in the Patient

(a) In the blood principally during the febrile periods although this is difficult

(b) At the site of the bite either by obtaining lymph or by section of the inflamed tissue

(c) In the lymph at the site of the exanthem

(d) In the lymph glands in the lymph as well as in sections of tissue

This gives the characteristic recurrent aspect to the fever curve Numerous variations can be produced however in the different paroxysms varying in different cases At times the period of recrudescence is often marked by a subfebrile state at times by a continuous fever

Exanthem—Exanthem is an almost constant finding in the development of the disease In some cases it is located so close to the site of the bite that it may almost be missed The tendency is toward generalization but it may be localized in certain regions without special or marked predilection for any one area

The type of lesion is rather variable It may be a simple macular lesion or maculopapular or papular or even nodular The general appearance resembles the cutaneous lesions of syphilis or rubeola

The color of the lesion may vary from pale pink to violet red and may even appear ecchymotic

The size of the lesion varies sometimes it is as much as an inch or more *in diameter There is no particular tendency to confluence* but *occasionally* this may occur in large patches with irregular borders

These exanthematous lesions show a very definite characteristic—they are painful with or without pressure Sometimes the pain may appear before the lesion is visible The lesions are not pruriginous

Spirilla may be found in lymph obtained from these lesions

The exanthem is marked in the febrile period and diminishes in intensity to the point of disappearance in the intermediate intervals As the disease progresses the exanthem becomes progressively lighter in intensity

Nervous Manifestations—Nervous manifestations sometimes characterize a clinical type of the disease when they are very marked The prognosis may be guided by the severity of the symptoms These may range from the mild disease to the most serious type There may be stupor exhaustion prostration and coma (in fatal cases) Such disturbances as paresthesias as well as motor disturbances characterized by dystonia may be present These disturbances may be exaggerated diminished or totally absent

Pain—Pain is always associated with location in the different muscle groups of the limbs abdomen and thorax also bones and joints may be affected

Symptoms in Other Organs—Certain organs are not affected by the disease among these are the heart spleen liver and lungs In general the disease does not follow typical or regular localizations

Some authors have reported the presence of spirilla in the urine suggesting localization of the disease in the kidney Although albuminuria is constant it is slight no other abnormal constituents appear in the urine

In some cases diffuse bronchitis may be present accompanying febrile paroxysms of the disease

As for involvement of the digestive apparatus symptoms include buccopharyngeal exanthem dysphagia anorexia nausea constipation etc Of these only the exanthem and dysphagia are of sufficient constancy to be clinically significant

and Parker Hitchens, 1939), *Actinomyces muris Topley and Wilson* (Wilson and Miles, 1946), and others Utilization of only one name for the infections caused by this organism will be of advantage in future investigation

Origin.—To date, *S moniliformis* has been isolated from different parts of the body such as the *blood and other secretions* and tissues in cases of bite by rats and other rodents the lungs of rats and other sick animals, the nasopharynx of laboratory mice, and *in cases in which* the infection has occurred through other means such as in Haverhill fever

Morphology—Morphology of this microorganism has been well described by various investigators (Levaditi, Litterer, Parker and Hudson, *etc*) *It is necessary to recognize* the fact that but few bacteria show such a high degree of pleomorphism

On *Loeffler's blood serum* fine branched filaments may be observed, about 0 5 micron in width, tending to intertwine, later, fragmentation of the filaments occurs, chains of *bacilli and coccoid forms* now appearing The term "moniliform" is adequate, since these filaments sometimes show a fusiform, oval, or spherical thickening, somewhat resembling Monilia These thickenings may have a diameter several times larger than the width of the filament and may project toward one side only The possibility of variation or association with a coccobacillus (organism L) described by Klieneberger (1935) is due to these phenomena

Fig 115 —*Streptobacillus moniliformis* from a 48 hour culture on Loeffler's blood serum medium First Cuban case (Courtesy A J Aballi and J A Martinez Cruz.)

Staining is irregular, it has been described as gram negative and again as gram positive, the latter mostly in young cultures

It is not motile and does not have acid or alcohol resistant forms

Cultural Characteristics—Addition of blood or serum is indispensable for cultivation *of the organism* *On Loeffler's medium* the colonies are light yellow, 0 5 to 0 7 mm in diameter They show a central somewhat elevated zone with a flattened periphery and irregular edges *There is no hemolysis* *They grow better* under anaerobic conditions and in a 10 per cent carbon dioxide atmosphere

Recent studies show that they produce acid slowly in glucose and *salicin* and sometimes also in maltose and lactose They do not form indole and do not change litmus milk, do not produce hydrogen sulfide, and do not reduce nitrates *They give negative results* with the methyl red and Voges Proskauer tests The catalase test is negative

Pathogenic Characteristics—Inoculation of laboratory animals, which is of *great diagnostic value, is effective* in mice which are very susceptible to this bacterium Rats, guinea pigs and rabbits are resistant The rabbit, however at times shows a few inflammatory *lesions, particularly* arthritis

(2) Inoculation of Susceptible Animals

In this case the guinea pig is preferred since it develops a rather typical experimental picture in which spirilla can be demonstrated (See above)

Inoculation of mice does not produce any pathologic picture but spirilla can be demonstrated in the blood and peritoneal fluid

One must keep in mind that spirilla are sometimes found in these laboratory animals

(3) Demonstration of Specific Antibodies in the Serum

Serum of patients or serum from convalescents can be tested for spirochetolytic and spirocheticidal substances This may be carried out long after the infection has passed and may serve in retrospect rather than for study of cases on hand The serum of the patient or a convalescent or a cured subject is used using as controls mice with spirilla in which dissolution and disappearance of the microorganisms have been observed

PROGNOSIS

Prognosis is generally favorable once the diagnosis has been established and adequate treatment applied Mortality is in the neighborhood of 10 per cent

TREATMENT

In 1912 Hata assuming the origin of the disease to be spirochetal recommended the use of arsenicals in treatment Some cases respond to this treatment with marked rapidity while others respond more slowly so that at times it is necessary to repeat a series before complete cure is obtained

A curious observation made by Cuban investigators (Anido Hernandez Rio Leon and Velasco) is that treatment is somewhat more effective when the disease is allowed to develop rather than when begun immediately upon diagnosis This observation is contrary to most experiences with most infectious diseases

Known antisyphilitic mercury and bismuth derivatives have been recommended and used by various authors although in general it is recognized that their action is not as effective as trivalent arsenicals

PROPHYLAXIS

Prophylaxis should be directed to the destruction of the reservoir of the disease that is against the rat This places the problem within the general scope of community sanitation and prophylaxis

INFECTION BY STREPTOBACILLUS MONILIFORMIS (HAVERHILL FEVER)

Streptobacillus Moniliformis (Levaditi)

Synonyms—The bacterium has been described under many different names among which the more important are *Streptothrix muris ratti* Schottmuller (1914) *Haverhillia multiformis* Parker and Hudson (19 6) *Act omyces act no des* Bergey (Bergey Breed, Murray,

Arthritis is as frequent a lesion and symptom as is the exanthem It appears soon after the beginning and is *generally associated with* pain generalized in the limbs especially in children The period of duration of the disease is variable in children it is more transient than in adults in whom it persists much longer sometimes for many years

Other manifestations may be present such as bronchitis cough and dysphagia

The course of the disease has the general character of the infection produced by the bite and occurs in outbreaks which generally recede only to return anew In almost every case the first period lasts from three to five days the patient returning spontaneously to a normal state It is precisely at the moment of the first remission that the exanthem appears After a lapse of two or three days a recrudescence takes place in which the exanthem is more pronounced and there are generalized symptoms of arthritis The process may show an intense or an attenuated development according to the *intensity of this latter manifestation* It may last for several days or weeks Later recurrence of symptoms is variable and is influenced by different forms of treatment

Streptobacillary Infection Due to Ratbite

The *site of the bite* so far as incidence of the infection is concerned does not make any difference in the processes

As to the *period of incubation* at first it was thought that the period was much shorter in the bacillary infection than in the spirillary type but an analysis of the literature shows that there is no essential difference since some cases of bacillary infection may appear quickly (in two or three days after the bite) whereas in others there has been a delay of as long as nine days and in some cases as long as fourteen days and even longer One observation reports a lapse of several months between the time of the bite and the onset of symptoms

The *onset of the disease* is sudden *with fever chills headache and vomiting* In this respect there is no essential difference in the two diseases

As to *local symptoms* the differences are of slight diagnostic importance Similar variations appear in both types Lymphangitis and adenitis may develop as in spirillary infection *though in the latter healing of the wound* between the time of the bite and the beginning of the disease may frequently be observed

Regarding *general symptoms* there is the fever which in a major part of the cases is not very high The fever is of markedly recurrent character although there are some cases in which this is not true In respect to this recurrent character of the fever there is no difference between the two forms of the disease

Exanthem is a symptom which is never absent and as in sodoku has been described by numerous authors It may have characteristics that are quite variable in the different cases The same is true of the spirillary form of the disease

Nervous manifestations show no marked difference in the two forms

Subcutaneous or intraperitoneal inoculation of the mouse is generally fatal within a period of seventy two hours without the production of any characteristic or special lesions The microorganisms are easily recovered by culture from the blood

Variants—There have been isolated from cultures of *S moniliformis* pure forms of an organism similar in appearance to those of the pleuropneumonic group Klieneberger (1935) considers these as symbiotic elements Other investigators (Dienes 1939, Smith 1918 and Brown and Nunemaker, 1942) consider it a variety of the same Streptobacillus

Transmission.—*S moniliformis* can be transmitted either directly by ratbite or indirectly, by means of contaminated food

In the first case the mechanism of the infection is analogous to that of sodoku disease in the second elimination of Streptobacillus in the secretions and excretions of Muridae may explain the mechanism

LABORATORY DIAGNOSIS

Diagnosis of infection due to *S moniliformis* cannot be considered a routine procedure It is based upon demonstration of the organism by culture methods or by inoculation of the mouse a highly susceptible animal and therefore the animal of choice

The Streptobacillus can be demonstrated in the blood of the patient Other body fluids from the patient depending upon the kind of lesion he presents (arthritis abscesses etc) may be used in cultures and inoculations to demonstrate the organism

When the growth in the cultures is sufficient some authors recommend agglutination tests using the serum of the patient from whom the bacillus was isolated Agglutinins when adequate antigen is used do not reach a high concentration but persist for a sufficiently long period of time in the individual

CLINICAL PICTURE

Haverhill Fever Not Caused by Ratbite

The period of incubation in the cases studied was short between one and three days This period is shorter than when infection occurs through a bite

The disease begins suddenly with chills vomiting headache and fever The last symptom is never absent the temperature rises to around 40° C in some cases

One to eight days later an exanthem appears this is one of the most constant symptoms of the disease and persists for a variable period This exanthem is seen principally in the anterior and lateral parts of the extremities One characteristic of this manifestation is that it is found especially around the joints The lesion although not in all cases may also appear in the face and the thorax The eruption resembles rubeola though at times it may be morbilliform Frequently the lesion is of maculopapular aspect dark red in color rounded outline at times with irregular margins varying greatly in form and size (between 1 and 4 mm in diameter), sometimes somewhat larger Petechial hemorrhages may appear in severe cases particularly on the extremities Desquamation is observed in some cases

& Wilkins Co

Changes in the blood are practically the same anemia moderate leucocytosis which may be elevated in some cases with increase in neutrophiles, and eosinophilia This last sign is very marked in sodoku

The most marked difference refers to arthritis however this manifestation together with osseous pains has been observed in experimentally inoculated sodoku (Solomon Berk Theiler and Clay 1926 Bayne-Jones 1927, Herschfeld Kibler Colby Koening Schmid and Saunders 1929)

Some authors have tried to establish differences which may be observed clinically between the two entities It is possible that in some aspects a great deal of observation and accumulation of data may do this but in our present state of knowledge we can see how the major part of the symptoms are superimposed and how some cases present variations which are the same in both processes For the moment it is best not to depend upon these data for classification and diagnosis without waiting for results of the bacteriologic investigation

PROGNOSIS

In general the prognosis is good Mortality observed in twelve cases in the United States of America has been 10 per cent

TREATMENT

Neither type responds to specific therapy Conclusions concerning the efficacy of the medicaments which have been used are difficult Autogenous vaccines and the sulfonamides have no action and information concerning these varies Salicylates iodine and quinine have been used with mediocre and equally irregular effect Arsenicals which have a marked action in sodoku show none here although they have not been tried sufficiently to warrant more certain conclusions

The impression gathered from the study of existing bibliography is that treatment is one of the points of difference in the two processes

PROPHYLAXIS

In cases of infection by *S moniliformis* due to ratbite prophylactic measures with slight variations will be the same as those considered in sodoku disease

In Haverhill fever or those cases of infection induced by mouth prophylactic measures should be in the direction of obtaining bacteriologic purity of foods principally milk and milk products The use of pasteurized milk is highly recommended

Trauma plays an important role in the transmission of framboesia. It *seems likely that the organisms must come in contact with an abrasion* in the skin in order to *initiate successful infection.* It is questionable whether or not they can penetrate the intact skin. *Many patients are able to give a definite history of some previous injury*, others are not. It is generally accepted that the location of the primary lesion is also the site of infection. Primary lesions occur most frequently on those regions of the body exposed and likely to be traumatized, namely the feet and legs. *The ankles (malleoli) and lower* third of the legs are the commonest sites of primary lesions. It is these parts of the body which are most frequently bruised, scratched or cut on persons walking among shrubs and grasses without shoes, stockings or trousers. The drying of mud on the feet and ankles and its subsequent removal is another probable source of abrasions. Crowded, unhygienic living conditions foster the spread of infection in family groups so that frequently all of the children and sometimes the adults in a family develop lesions.

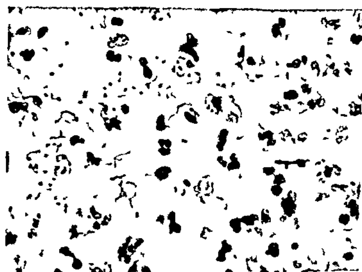

Fig. 116.—*Treponema pertenue* in the epidermis (X970.)

Persons of all ages are susceptible to infection with *T. pertenue*. However in most parts of the world yaws occurs most commonly in children.

The explanation for the higher incidence in children than in adults appears to be mainly in the development of immunity by the latter as the result of previous infection. Contributing factors may be that adults and older children are generally better clad and that adults do not come in direct contact with one another to the same extent as children. Considerable epidemiologic and experimental evidence, *both animal and human, supports* the general belief that among inhabitants of areas where the disease is endemic one attack confers protection against a second. Immunity develops slowly and progressively over a period of years but ... to persist for many years even in the absence of manifest lesions of ... m ch

CHAPTER 16

FRAMBOESIA (YAWS)

ALBERT JOHN SHELDON

Synonyms.—Yaws (English) and pian (French, Spanish, and Italian). Colloquial names: "buba" or "boubas" (Brazil and the Dominican Republic), "cuchipe" (Ecuador), "coko" or "coco" (Fiji Islands), "tonga" (New Caledonia), "puru" or "purru" (Malaya), "lupani" or "tono" (Samoa), "parangki" or "parangi" (Ceylon), "patek" (Java), "momba" (Angola), and "dube" (West Coast of Africa).

CAUSAL AGENT

Treponema Pertenue (Castellani 1905)

The organisms measure 12 to 20 microns in length and have 8 to 20 small, broad turns in the spiral. They are morphologically indistinguishable from *T. pallidum*, the etiologic agent of syphilis. Motility is accomplished by translation in the direction of the long axis, a rotary movement of the spirals, giving the impression of a corkscrew turning on its own axis, and a waving or twisting movement from side to side. The organisms are readily killed by drying and cannot withstand exposure to air and light more than twenty-four hours in a moist medium. Cultivation is difficult, if not impossible.

The spirochetes are present in large numbers in primary and secondary lesions and have been demonstrated in lymph glands, spleen, and bone marrow. They have not been found in the blood stream, but Castellani (1907) successfully infected apes by injecting blood from framboesia patients. Further evidence of their presence in the blood stream is the dissemination of the secondary lesions over the entire body. Organisms have never been demonstrated in deep organs other than those mentioned above, nor in the nodular, ulcerative, scaling, or gummatous lesions of the tertiary stage of the disease. Monkeys and rabbits, as well as apes, can be experimentally infected with framboesia. Hamsters are also susceptible.

T. pertenue organisms are readily transmitted from infected persons to others by direct contact, resulting in a high degree of communicability. Indirect contact with contaminated clothing, bedding, sleeping mats, utensils, furniture, soil, etc., is probably a less important means of spreading disease because of the marked fragility of the organisms. Kumm (1935) showed that mechanical transmission by the minute "gnat" fly, *Hippelates papillipes*, is possible within seven hours after feeding on open framboesia lesions by regurgitation of ingested material containing spirochetes. Venereal transmission does occur but is only incidental. Moss and Bigelow (1922) stated that primary lesions appeared on the genitals in only 1 per cent of 969 cases in the Dominican Republic. In Jamaica, Chambers (1938) reported that less than 3 per cent of 580 primary lesions were located on the genitals, mostly in children under 7 years of age. Autoinfection may occur during the early course of the disease. Lesions frequently spread locally and to opposing contiguous surfaces, particularly around the mouth, anus, and vagina. It is generally believed that congenital infection does not occur. However, Hunt and Johnson (1923) found cases of interstitial keratitis among framboesia patients in Samoa where syphilis does not exist among the natives.

Haitians and Jamaicans and sporadically among Dominicans In 1944, 14,834 cases were reported to the health authorities, and 7,891 were reported through July, 1945

Ecuador—Villagómez (1932) reported that half of the 30,000 inhabitants of the Province of Esmeraldas were infected with framboesia Seventy two cases were reported to the health authorities during the period January August, 1945

Guatemala—Bolaños and Selva (1934) reported having observed three cases of framboesia in Chocolá in 1931 Later many more cases were found in Madre Mia (near Chocolá) in San Pedro Jocopilas, Santo Tomás, La Unión, and Samayac, all neighboring municipalities

Haiti—McKinley (1935) stated that 100,000 cases of framboesia had been reported, the majority from rural districts During 1943, 48,759 cases were reported to the health authorities, 32,195 were reported in 1944, and 11,679 were reported during the period January July, 1945 Duvalier (1945) reported that 97,291 patients attended one rural clinic in Haiti from March, 1943, to March, 1944

Jamaica—Saunders et al (1936) found that framboesia was present in large numbers of persons in St Thomas, Portland, St Mary, St Catherine, Clarendon, St. Elizabeth, and St. James Turner and Saunders (1935) recorded an incidence of 58 per cent in the Bath area and 47 per cent in the Seaforth area.

Nicaragua—Lacayo (1935) reported four cases in Managua

Panama—Brosius (1930) stated that framboesia is uncommon in Almirante where he treated only 12 cases in the previous five years and 4 cases in 1930 Wilson (1934a) reported 424 cases in the province of Darien Later the same year (1934b) he noted an average incidence of 16 4 per cent among five villages near the confluence of the Chagres and Gatuncillo Rivers, about 50 kilometers from the capital city Seven hundred sixty four cases were reported to the health authorities in 1944, and 84 during January June, 1945

Puerto Rico—Gotay, Costa, Mandry, and Payne (1935) found 94 cases among 1,091 inhabitants of a rural section

Venezuela—Cases have been reported from the States of Miranda, Aragua, Guárico, Carabobo, Cojedes, Yaracuy, Portuguesa, Zulia, Trujillo, Mérida, Táchira, Anzoátegui, Sucre, Nueva Esparta, and Bolivar Vegas, Lovera, Itriago, and Medina (1943) reported 24 5 per cent of 236,793 persons infected in Carabobo In 1944, 2 124 cases were reported to the health authorities, and 828 were reported during the period January April, 1945

There is a high incidence of framboesia in equatorial *Africa*, particularly in Liberia, the Gold Coast, Nigeria, French Equatorial Africa, the Belgian Congo, and Angola on the west coast, and in Kenya, Tanganyika, Zanzibar, and Mozambique on the east coast It is common on the Comoro Islands and Madagascar The incidence is fairly high in the Anglo Egyptian Sudan, Uganda, Rhodesia, and Nyasaland There is a low incidence in Algeria, Tripoli (Libya), Egypt, and Kimberley (South Africa)

In *Asia* the incidence of framboesia is high in Assam (India), Burma, Thailand or Siam, French Indo China, Malaya, the Netherlands Indies, and the Philippine Islands It is rare in Bengal and Travancore (India) and is said to be disappearing from Ceylon The incidence in southern China is very low

Framboesia is common in *northern Australia* and on a number of the *Pacific Islands*, namely, Samoa, New Hebrides, New Caledonia, Fiji, Gilbert, Ellice, Caroline, Marianas, and others

PATHOLOGY

Framboesia is characterized by a variety of lesions, some of which tend to occur in a certain sequence Chambers (1938) suggested the following arrangement of the lesions

A Primary stage
  1 Single skin granuloma ("maman pian," "madre buba," or "mother yaw")
  2 Single skin macule or macular patch ("yaws spot")

Secondary skin lesions begin, according to Goodpasture (1923), with a localization of spirochetes *from the blood* in certain papillae from which points the organisms infect the epidermis where conditions appear to be *more favorable* for their growth. The early macule shows only slight hyperkeratosis with thinning of the epidermis due to edema and enlargement of the papillae. At a later stage keratinization increases, small foci of spongiosis appear, plugging of follicles occurs and there is beginning infiltration of plasma cells and

Fig 117.—Framboesiform lesion (×50.) This section shows marked elongation of pegs necrosis of superficial epidermis and intraepidermal abscesses (From Ash and Spitz Pathology of Tropical Diseases W B Saunders Co By permission of the authors and publisher)

lymphocytes, few organisms are present. The papule represents the nonulcerative transitional stage between the macular and the typical framboesiform lesion. In it cellular infiltration is more marked and there are more organisms present in the epidermis than in the macular lesions. The framboesiform lesions closely resemble the primary lesions but are frequently smaller and are covered with yellow crusts. Removal of the crust reveals a superficial ex

B Secondary stage
1 Macular skin lesions with scaling with or without depigmentation
2 Folliculopapular skin lesions
3 Papular skin lesions
4 Framboesiform skin lesions (button yaws')
5 Joint lesions
6 Bone lesions
7 Plantar and palmar skin lesions nonulcerative type
8 Plantar and palmar skin lesions ulcerative granulomatous type (' crab yaws' or ' clavus)
9 Delayed or late plantar and palmar skin lesions
10 Delayed or late bone lesions

C Tertiary stage
1 Nodular skin lesions
2 Ulcerative skin lesions (gumma)
3 Circinate scaling skin lesions (ringworm yaws)
4 Pigmentary skin changes
5 Gummatous lesions of skin and bone
6 Juxta articular nodules
7 Goundou
8 Gangosa
9 Cardiovascular lesions (doubtful)
10 Neurologic lesions (doubtful)

The histologic picture of the various primary and secondary skin lesions as described by Ash and Spitz (1945) is essentially the same allowing for differences in intensity and duration of the tissue reaction and for anatomic differences at the site of the lesion The primary lesions are granulomatous with edema and hyperplastic changes in the epidermis and enlargement and elongation of the rete pegs In lesions one to two months old the superficial portions of the epidermis are usually necrotic and the lesions are covered by crusts composed of keratin debris leucocytes blood and dried serum Underlying this layer there is often a parakeratotic plaque Hyperkeratosis is always present and scattered epithelial pearls and plugged follicles are common The pegs are elongate and irregular presenting a characteristic interlacing branched appearance There is a marked degree of spongiosis and intracellular edema Small intraepidermal vesicles and abscesses are common especially adjacent to similar foci in the papillae Pigment is usually absent from the epithelium In places the elongated papillae protrude through the epidermis which is thin or absent The upper papillary layer is edematous and hyperemic and the lymphatics are dilated The granulomatous infiltrate present in the lower papillary and subpapillary layers is composed mainly of plasma cells and lymphocytes with scattered polymorphonuclear leucocytes and eosinophiles Small vessels are not involved Spirochetes are numerous in the epidermis especially in the granular and basal layers They are occasionally seen in the crusts but are seldom found in the lower segments of the dermis

Fig 118 —Primary lesion of framboesia on external malleolus.

Fig 119 —Same lesion as shown in Fig 118 one week after treatment with 1 200 000 Oxford Units of penicillin

coriation with clean cut edges. It is lined with granulation tissue which bleeds readily. Plantar and palmar skin lesions also resemble the primary lesion except for their persistence which is probably due to the continuous trauma to which they are subjected and the thickness of the epidermis in these areas.

The histology of the tertiary lesions is not well known except in the case of subcutaneous gummas. These show necrosis of tissue and ulceration of the overlying skin. The necrotic area is surrounded by a zone of epithelioid cells and numerous giant cells. Spirochetes are sometimes found in small numbers in these lesions. The gummas are similar to those of syphilis. The juxta-articular nodules show nonspecific granulomatous processes with central necrosis and a peripheral border of epithelioid cells in which numerous giant cells are scattered. Bone lesions evince periosteal proliferation and dense areas of sclerosis. Osteitis may result in a "sabre shin" or produce deformities of the arms or fingers. In gangosa the nasal cartilages may be completely destroyed. The presence of visceral lesions is debatable. Choisser (1929) reported a series of 700 consecutive autopsies in Haiti. In 10 cases which he considered to be definitely framboesia, 8 had aneurysms of the aorta, 1 a gumma of the brain, and the other a spontaneous cerebral hemorrhage. He was unable to differentiate the pathologic process in these lesions from that of syphilis which is also prevalent in Haiti.

CLINICAL SIGNS AND SYMPTOMS

Framboesia runs a comparatively mild clinical course which may be arbitrarily divided into the same three stages described for the pathologic lesions. It rarely results in death, although some untreated or inadequately treated patients may show marked cachexia. A relatively small proportion of cases may develop large destructive and disfiguring late skin and bone lesions, usually accompanied by secondary bacterial infection.

Incubation Period

The incubation period varies from three to six weeks. Frequently the primary lesion is ushered in with prodromal systemic symptoms, such as vague abdominal discomfort, nocturnal headache, joint pains, and an irregular fever. These symptoms often abate upon the appearance of the initial lesion. As previously stated, the primary lesion occurs most frequently on the feet, particularly the malleoli; less common sites are the legs and knees, especially on the anterior aspect of the lower third of the legs. The head, neck, thighs, upper extremities, and genitals are much less frequently involved. The location of the primary lesions does not appear to influence the course of the disease. Some patients are unable to give a history of a primary lesion. In such cases either the lesion was so small it was overlooked or it did not develop, the disease beginning with secondary lesions. Chambers (19 8) reported that in Jamaica there was an increase in primary lesions during the wet seasons, indicating that environmental conditions are more favorable for the spread of infection at those times.

Fig 118 —Primary lesion of framboesia on external malleolus.

Fig 119 —Same lesion as shown in Fig 118 one week after treatment with 1 200 000 Oxford Units of penicillin

Primary Lesion

At the end of the incubation period the primary lesion appears as a small elevated papule a few millimeters in diameter or as a group of papules It occasionally begins as a tiny macule which may go unnoticed In a few days the lesion enlarges to the size of a small pea and becomes surrounded by an inflammatory areola The epidermis begins to crack open and a yellowish seropurulent fluid exudes from the underlying granulomatous base The papule continues to enlarge daily and may attain a diameter of 2 to 6 cm or more apparently depending upon the size of the pre existing injury After a week the surface becomes covered by a dark crust which oozes serum and bleeds easily The lesion is usually painless It may go through the stage of scab formation and healing in two to four weeks prior to the appearance of the secondary lesions More often as the result of secondary infection it persists with the secondary lesions for weeks months or years Frequently it breaks down to form an ulcer with a granulating base and raised edges As a rule the primary lesion eventually heals leaving a noticeable scar which may endure throughout the life of the patient

Secondary Stage

The secondary stage manifests itself as a generalized eruption from two weeks to three months after the appearance of the primary lesion The average time interval between the two stages is from three to four weeks The variation in time may be the result of a number of factors the number of organisms causing infection repeated inoculations the virulence of the organisms and the extent of trauma at the site of inoculation Transitory prodromal symptoms of fever malaise headache and joint pains are again generally present A slight rise in temperature of one to two degrees Fahrenheit often precedes and accompanies the secondary eruption persisting until after the lesions have begun to recede and fresh ones no longer appear The joint pains are not generally accompanied by heat or swelling

The secondary lesions may be profuse over the face limbs buttocks and trunk Occasionally they may be distributed scantily in one or two places or they may not be present at all They are generally more numerous on the buttocks and thighs In many cases lesions appear at the mucocutaneous borders of the nose mouth anus and vagina and on the scrotum and penis Lopez Rizal and Sellards (1926) reported a modification of secondary lesions in a group of patients living in the mountains of Northern Luzon Philippine Islands The lesions were limited to the mucocutaneous junctures of the mouth nose anus and genitals in approximately 90 per cent of the cases This limitation of distribution of lesions has not been observed in patients residing in the mountainous regions of Haiti or Jamaica Mucocutaneous lesions of the mouth occasionally spread directly to the mucous membrane of the lips

The secondary lesions have the same characteristics as the primary lesions Typically desquamating macular lesions are the first to appear In a few days

elevated papules develop in some of the macular areas. *They increase rapidly* in size, the majority obtaining a diameter of from 2 to 4 cm. Itching occasionally accompanies the lesions. Dried serum and dead *epithelium form a* soft yellow crust. Later the crust may become dark yellow, harden and become friable, assuming a characteristic heaped up *appearance. Lesions around* the mouth and nose frequently remain moist and soft. In the genital, anal and perianal regions some lesions may be *condylomatous and others some*what flattened from pressure and are moist. In all the above locations the lesions are not usually painful, but those on the soles of the feet and the palms

Fig 120

Fig 121

Fig 120.—Papular lesions in the secondary stage of framboesia.
Fig 121.—Same patient as shown in Fig 120 one week after treatment with 1,200,000 *Oxford Units of penicillin*

of the hands may be extremely so. The lack of large amounts of loose subcutaneous connective tissue in these areas results in the development of pressure symptoms. Regional lymphadenopathy frequently occurs. The generalized eruption may persist for months or years, coming out in successive crops in long standing cases. In addition to, and occasionally in the absence of the framboesiform eruption some patients may show *papulofollicular* lesions. These appear early as discrete round or ovoid elevations on the skin *0.5 to 1.5 cm in diameter. At times the framboesiform* lesions are circinate. Fox (1943) mentioned an infrequent early secondary eruption consisting of pinhead sized papules in groups which has been called "keratoid yaws" be

Primary Lesion

At the end of the incubation period the primary lesion appears as a small elevated papule a few millimeters in diameter or as a group of papules It occasionally begins as a tiny macule which may go unnoticed In a few days the lesion enlarges to the size of a small pea and becomes surrounded by an inflammatory areola The epidermis begins to crack open and a yellowish seropurulent fluid exudes from the underlying granulomatous base The papule continues to enlarge daily and may attain a diameter of 2 to 6 cm or more apparently depending upon the size of the pre-existing injury After a week the surface becomes covered by a dark crust which oozes serum and bleeds easily The lesion is usually painless It may go through the stage of scab formation and healing in two to four weeks prior to the appearance of the secondary lesions More often as the result of secondary infection it persists with the secondary lesions for weeks months or years Frequently it breaks down to form an ulcer with a granulating base and raised edges As a rule the primary lesion eventually heals leaving a noticeable scar which may endure throughout the life of the patient

Secondary Stage

The secondary stage manifests itself as a generalized eruption from two weeks to three months after the appearance of the primary lesion The average time interval between the two stages is from three to four weeks The variation in time may be the result of a number of factors the number of organisms causing infection repeated inoculations the virulence of the organisms and the extent of trauma at the site of inoculation Transitory prodromal symptoms of fever malaise headache and joint pains are again generally present A slight rise in temperature of one to two degrees Fahrenheit often precedes and accompanies the secondary eruption persisting until after the lesions have begun to recede and fresh ones no longer appear The joint pains are not generally accompanied by heat or swelling

The secondary lesions may be profuse over the face limbs buttocks and trunk Occasionally they may be distributed scantily in one or two places or they may not be present at all They are generally more numerous on the buttocks and thighs In many cases lesions appear at the mucocutaneous borders of the nose mouth anus and vagina and on the scrotum and penis Lopez Rizal and Sellards (1926) reported a modification of secondary lesions in a group of patients living in the mountains of Northern Luzon Philippine Islands The lesions were limited to the mucocutaneous junctures of the mouth nose anus and genitals in approximately 90 per cent of the cases This limitation of distribution of lesions has not been observed in patients residing in the mountainous regions of Haiti or Jamaica Mucocutaneous lesions of the mouth occasionally spread directly to the mucous membrane of the lips

The secondary lesions have the same characteristics as the primary lesions Typically desquamating macular lesions are the first to appear In a few days

difficult and resembles the locomotion of a crab A week or two later the lesions ulcerate and become slightly less painful These lesions tend to remain longer than other secondary lesions and are less responsive to treatment They may continue to appear for years after other secondary lesions have healed Nonulcerative plantar lesions often develop late in the course of the disease sometimes several years after the first attack

During the secondary stage there may be definite bone involvement The tibiae are most commonly affected then the ulnae radii fibulae tarsals metatarsals metacarpals carpals phalanges of fingers and toes and humeri in descending order of frequency The maxillae, clavicles frontal bone

Fig 124 Fig 125

Fig 124 —Circinate framboesiform lesions of the face
Fig 125 —Same patient as shown in Fig 124 one week after treatment with 600 000 Oxford Units of penicillin

femora sternum scapulae and patellae are more rarely affected Paronychiae with periosteal and bone involvement may occur A fusiform or nodular swelling develops over some part of the bone Pain is usually present and may be felt before there is any palpable swelling Gross bone deformity may develop if treatment is not begun early or if it is inadequate

After reaching a certain stage of development the various types of primary and secondary lesions usually begin to regress in the absence of treatment Healing appears to take place by the process of dehydration Exudation diminishes and the crusts disintegrate The hyperkeratotic epidermis is

cause of its supposed similarity to keratosis pilaris He suggested it more closely resembles lichen scrofulosorum

The plantar and palmar skin lesions ("crab yaws") are a distinctive feature of framboesia They are the counterpart of the characteristic generalized eruption The lesions appear as punctate erosions giving the soles

Fig 122

Fig 123

Fig 122 — Flat moist framboesiform lesions on the genitalia
Fig 123 — Flat moist framboesiform lesions in the perianal region

and palms a moth eaten appearance The affected areas are thicker drier and harder than normal as the result of marked hyperkeratosis and desquamation Fissures frequently accompany the lesions The soles and palms become tender and painful Plantar lesions may be so painful that walking becomes

shed and the skin resumes its normal appearance Increased pigmentation and occasionally depigmentation may persist for months As a rule primary lesions leave scars secondary lesions do not

Tertiary Stage

The majority of framboesia cases do not progress beyond the secondary stage *so far as is known* a few cases do not go beyond the primary stage The tertiary stage develops in a few of the untreated or inadequately treated patients in from one to several years after the initial lesion Sometimes the secondary and tertiary stages merge or the interval between the two may be so

Fig 129—*Late* bone lesions in framboesia accompanied by disfigurement and wasting

long that it is difficult to get a reliable history A variety of lesions have been ascribed to the tertiary stage Ulcerative lesions *on* the legs seem to be most common some of which are of a spreading superficial type and others deep They frequently develop at the site of the primary lesion or in close proximity to it The edges of the superficial ulcers *are* usually raised and serpiginous the edges of the deep ulcers are often undermined *The base of* the ulcer

Fig 1²6

Fig 127

Fig 126 —Ulcerati e pl ntar les on (crab ya s) of frambœsia
Fig 127 —Same patient as sl own in Fig 1²6 one eek after treatn ent with 1 200 000 ord Units of penic ll n

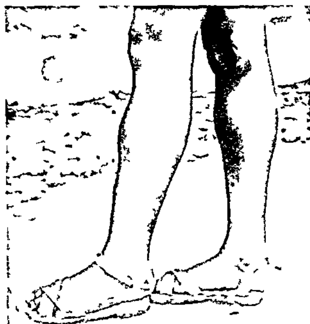

Fig 1²8 —Bowing of t biae due to frambœsia.

Juxta articular nodules occur even less *frequently than gangosa* They appear as firm freely movable painless subcutaneous masses varying in size from 1 to 3 cm They occur most commonly on the extensor aspects of the elbow and knee joints and less frequently over the external malleoli tempero mandibular joints finger joints trochanters and sacrococcygeal joint They *seem to develop in localities which* are most often subjected to pressure and to repeated trauma The lesions persist for years and the skin over them may become attached Suppuration is rare

Goundou is considered to be a rare form of tertiary lesion which like gummas gangosa and juxta articular nodules appears to be most prevalent in areas where treatment facilities are scarce It develops earlier than other tertiary lesions sometimes closely following secondary lesions in young chil *dren It is initiated by exostosis of the frontal process of the maxilla usually* bilateral The lesion may be accompanied by headache and a thin puru lent nasal discharge often tinged with blood As it progresses over a period of months it may involve the nasal and frontal bones producing a large oval tumor The overlying skin is not affected In some cases the nasal passages are obstructed

Some writers feel that framboesia may produce neurologic and cardio *vascular lesions in its late stages Wilson and Mathis (1930) observed 1 493* consecutive cases in Haiti and stated that ptosis blindness and optic neuritis were occasionally encountered No spinal fluid changes have been detected With reference to cardiovascular lesions none have been reported where other causal agents such as syphilis and rheumatic fever have been completely ruled out

DIAGNOSIS

The most important disease to be considered in the differential diagnosis of framboesia is syphilis particularly in the tertiary stages Little aid can be obtained from the laboratory since the etiologic agents are indistinguish able and specific serologic tests are positive in both diseases Spirochetes can readily be demonstrated by dark field microscope examination of serum from primary and secondary framboesia lesions after *removal of the crusts* The Wassermann (complement fixation) Kahn (flocculation) and other specific *serologic tests are positive in over* 99 per cent of patients with early fram boesia The tests become positive two to three weeks after the appearance of the primary lesion The titer increases rapidly and becomes strongly positive during the fifth or sixth week The tests remain positive for months or years occasionally becoming negative in the tertiary stage

DIFFERENTIAL DIAGNOSIS

There are a number of points to be considered in the differential diagnosis of framboesia and syphilis

1 Framboesia is prevalent in many rural areas where syphilis is prac tically unknown while in cities where there may be a great deal of syphilis framboesia is uncommon Wilson (loc cit) observed that in Panama and dif

is generally granulomatous A profuse serous or serosanguineous exudate is present Most ulcers are secondarily infected so that their appearance is altered and a purulent exudate is the rule Healing is slow and may leave disfiguring scars which interfere with function of the affected area particularly around joints

Gummas usually start as small firm subcutaneous nodules After a period of weeks or months the skin over the nodule becomes red and subsequently ulcerates producing a punched out lesion A serosanguineous exudate appears Healing may take place in a few months with extensive scar formation and disfiguration of the skin or the ulcer may become secondarily infected and persist for many months or years Occasionally the gummas are arranged in circles and are spoken of as "ringworm yaws"

Fig 130 —Early gangosa

Fig 131 —Advanced gangosa

Gangosa appears to be initiated by the spread of infection from the upper lip or vestibule of the nose to the mucous membranes of the soft palate or the nasal passages The membrane ulcerates and the process advances destroying soft tissues bone and cartilage The septal cartilage and the structures of the nose are lost leaving a cavernous opening The process may spread to involve the adjacent parts of the upper lip and cheek On occasion it seems to spread to the eyes by way of the nasal ducts Secondary infection probably plays an important role in modifying the appearance of the lesions The incidence of gangosa in areas where framboesia is highly endemic is less than 1 per cent

A number of other skin conditions are to be differentiated from framboesia Some of the more common are as follows

1 **Pyodermas** occur frequently in tropical countries A variety of types of lesions are seen pustules bullae vesicopustules folliculopustules furuncles carbuncles paronychiae and ulcers The principal etiologic agents are staphylococci and streptococci The majority of these can be readily recognized clinically However some become covered with *yellow or honey colored* crusts closely resembling secondary framboesia lesions others ulcerate simulating tertiary framboesia The crusted lesions can be differentiated by dark field microscope examination but the ulcers cannot since it is difficult to demonstrate spirochetes in framboesia ulcers The pyogenic ulcers usually have sharp sloping edges with a foul necrotic base as compared with the *undermined* edges and granulomatous base of the framboesia ulcers However, framboesia ulcers are often secondarily infected so that it is impossible to differentiate them from pyogenic ulcers *Borrelia vincenti* fusiform bacilli and *T refringens* may be found in the ulcers in addition to the pyogenic cocci The so-called tropical ulcers probably fall into this category Differentiation of ulcers is sometimes possible by response to the type of treatment instituted In general pyogenic ulcers will respond to local treatment and framboesia ulcers to specific treatment

2 **Scabies** is frequently seen in the tropics Its characteristic distribution on the webs of the fingers flexor surface of wrists axillae lower part of the abdomen and back and penis and scrotum serves to differentiate it from framboesia Itching is a prominent symptom which is not the case in framboesia Scabies may be complicated by pyogenic *infection or framboesia* making diagnosis more difficult Demonstration of the parasitic mite *Sarcoptes scabiei* by microscopic examination of scrapings from the lesions is not always possible

3 A number of **fungus infections** produce lesions resembling those of *framboesia*

a *Trichophytosis dermatophytosis* or *epidermophytosis* of the hands and feet may be differentiated from framboesia by their limited distribution and the presence of vesicles in the early acute stage of infection Microscopic examination of fungus elements in a potassium hydroxide preparation will *confirm* the diagnosis

b *Tinea versicolor* or *pityriasis versicolor* is characterized by yellow or brown irregularly sized finely scaling macules over the shoulders chest, upper portion of the back axillae and upper part of the abdomen *The etiologic agent Microsporon furfur*, can easily be seen in a potassium hydroxide preparation

c *Onychomycosis* or *"ringworm"* of the nails affects both toenails and fingernails the former more frequently The nail becomes friable thickened deformed and discolored Paronychial inflammation is uncommon The lack of accompanying *skin lesions tends to differentiate* this condition from framboesia

ferent parts of the world where a high incidence of framboesia is found the incidence of syphilis is correspondingly low

2 Framboesia is probably not congenital whereas syphilis definitely is giving rise to Hutchinsonian teeth bossing of the frontal bones iritis interstitial keratitis etc Framboesia does not cause abortion in pregnant women and children born to infected mothers do not show lesions or positive serologic tests

3 The primary lesion of framboesia is usually extragenital In syphilis the initial lesion is on the genital organs in a majority of the cases

4 The primary lesion of syphilis is often indurated and is not usually covered with a friable crust thereby differing from framboesia

5 Regional lymphadenopathy is generally more marked in framboesia than in syphilis and the glands are less firm and nodular

6 A history of the primary lesion and evidence of its presence in the form of a scar are more often obtainable in framboesia than in syphilis

7 The characteristic secondary lesions in framboesia covered with heaped up friable yellow crusts have not been observed in syphilis

8 Mucous membrane lesions are common in syphilis but not in framboesia except when direct spread from a cutaneous border is evident

9 The typical painful scrub yaws lesions on the soles of the feet and the palms of the hands in framboesia apparently do not occur in syphilis

10 Alopecia is sometimes seen in syphilis but has not been reported in framboesia

11 Gangosa and goundou occasionally develop in the late stages of framboesia but not in syphilis

12 Visceral lesions do not appear to develop in framboesia whereas they are not uncommon in syphilis In this category fall such lesions as gummas of the liver testes and kidneys neurologic involvement including meningitis hemiplegia arteriosclerosis tabes dorsalis and general paralysis and cardiovascular lesions such as aortitis myocarditis and aneurysm

13 Spinal fluid changes are a feature of syphilis but not of framboesia Spinal fluid Wassermann and Kahn tests are negative in cases of framboesia

14 A reciprocal immunity seems to exist between framboesia and syphilis. Schobl and Miyao (1929) and Schobl (1930) showed that a high degree of immunity to framboesia protected Philippine monkeys against cutaneous infection with syphilis and vice versa In human experiments Turner (1936) reported unsuccessful attempts to infect ten patients with latent syphilis by inoculation of *T pertenue* With regard to experimental infection of framboesia patients with syphilis only one instance is reported in the literature (Charlouis 1881) It seems likely that in such instances insufficient time had elapsed for the development of immunity

15 There is considerable experimental evidence that *T pallidum* possesses pathogenic properties in rabbits which differ from those of *T pertenue* and these may in part explain the differences between framboesia and syphilis in man (Pearce and Brown 1925 Turner and Chesney, 1934)

nosis of framboesia Definitive diagnosis of leishmaniasis depends upon the demonstration of *Leishmania tropica* in smears or cultures made from the lesions

5 **Mucocutaneous leishmaniasis** ("espundia") is widely distributed throughout Central and South America Ulceration about the margins of the nose and mouth may resemble gangosa Here again definitive diagnosis of leishmaniasis depends upon the demonstration of the etiologic agent *Leishmania braziliensis* in smears or cultures made from the lesions This is difficult in advanced cases with extensive secondary infection

6 **Seborrhea or seborrheic dermatitis** may be confused with the macular scaling lesions of the secondary stage of framboesia Its distribution characteristically corresponds to the areas of sebaceous gland concentration that is scalp mid portion of the face and presternal and interscapular regions Mild to severe dermatitis may occur in the intertriginous areas of the axillae umbilicus crural folds and gluteal cleft In questionable cases the demonstration of spirochetes on dark field microscope examination will establish the diagnosis of framboesia

7 **Pityriasis rosea** is a common papulosquamous eruption which may resemble the early secondary stages of framboesia Its distribution is typically over the back chest abdomen arms and thighs The lesions tend to be arranged with the long axis along the lines of cleavage They do not go through the course of development characteristic of framboesia lesions

8 **Lichen planus** may simulate some of the papular lesions of the secondary stage of framboesia The lesions frequently appear on the wrists forearms buccal mucosa and genitals They are generally violaceous flat topped and angular Itching is usually severe Here again the lesions do not go through the course of development characteristic of framboesia

9 **Psoriasis** may occasionally produce framboesiform lesions The typical psoriatic papule or plaque has a dull red base which is covered with a silvery moderately adherent scale The distribution is characteristically on extensor surfaces It is extremely chronic and like the secondary stage of framboesia does not usually leave scars Removal of the crust reveals a shiny red surface which is unlike the granulomatous base of the framboesiform lesions

10 **Acne vulgaris** in the papular and pustular stages may be confused with the secondary stage of framboesia The lesions are typically located on the forehead cheeks chin upper chest shoulders and upper portion of the back It is common in adolescents The lack of evidence of a primary lesion and the duration of lesions serve to differentiate this disease from framboesia

11 **Lupus vulgaris** is a form of tuberculosis of the skin which may simulate secondary and tertiary framboesia It is characterized by plaques of small soft applebutter like" tubercles Satellite nodules develop and then coalesce to form irregular groups of various sizes The face particularly the nose is most frequently involved The course is slow but progressive The lesions generally break down and form small crusted ulcers which are ultimately replaced by fibrous tissue The scarring is usually thicker and firmer

d *Tinea cruris* or "*ringworm*" of the groin ("dhobie itch") involves the upper inner surfaces of the thighs the inguinal folds and occasionally the scrotum buttocks intergluteal folds umbilicus and axillae The lesions appear as well marginated reddish patches with a slightly scaling surface They often tend to clear in the center with a papular or finely vesicular scaling border The localization and appearance of these lesions is generally sufficient to establish the diagnosis

e *Tinea corporis* or *ringworm'* of the body may appear in the form of circinate and annular red scaling lesions with an inflammatory reaction and active vesicular borders or as large irregular plaque like lesions with sharp borders and no vesiculation Fungus elements can usually be demonstrated in potassium hydroxide preparations

f *Tinea barbae* or *ringworm* of the face is a pustular folliculitis with induration and sometimes canalization The hairs of the bearded region become loose and are easily removed The presence of fungus elements in potassium hydroxide preparations establishes the diagnosis

g *Blastomycosis* is a more serious fungus infection occurring in North and South America which may have both cutaneous and systemic manifestations The skin lesions usually occur on the face neck hands wrists arms feet or legs They start as papules or pustules which develop into chronic ulcers There is usually little pain tenderness systemic reaction or regional lymphadenitis Diagnosis can be made only by demonstrating the characteristic budding organisms *Blastomyces dermatitidis* or *B brasiliensis* in pus from the lesions or in histologic sections

h *Sporotrichosis* is a chronic granulomatous fungus infection producing gumma like skin nodules ulcers and abscesses Diagnosis is based upon the cultural characteristics of the etiologic agent *Sporotrichum schenckii* after inoculation of infected material on Sabouraud s medium and inoculation into laboratory animals (rats mice and guinea pigs)

i *Actinomycosis* is a chronic suppurating granulomatous fungus infection of the skin characterized by multiple abscesses and fistula formation It is most frequently seen about the face and neck (lumpy jaw) The characteristic yellow granules of *Actinomyces bovis* can be readily demonstrated in the pus from the lesions by microscopic examination

j *Maduromycosis* or *Madura foot* is a chronic granulomatous fungus infection usually limited to the lower extremities producing extensive destruction of the soft tissues and the bony structures particularly of the feet In advanced cases the foot becomes a mass of cyst like areas with intercommunicating sinus tracts and multiple externally draining sinuses The characteristic granules of *Actinomyces* and branching mycelia of *Nocardia* and *Monosporium* can be demonstrated in potassium hydroxide preparations of pus

4 **Cutaneous leishmaniasis** (Oriental sore forest yaws ') occurs in many areas where framboesia is endemic Ulcers develop on the legs and arms which may closely resemble the primary lesion of framboesia The subsequent development of widespread secondary lesions establishes the diag

Arsphenamine (Salvarsan)

The chemical base is 3,3′ diamino 4,4′ dihydroxyarsenobenzene, marketed as the dihydrochloride salt containing about 31 per cent arsenic in the trivalent form. It is given intravenously in doses equivalent to 0.010 Gm per kilogram of body weight. The average single therapeutic dose is 0.40 Gm for men and 0.30 Gm for women. The drug is prepared by dissolving the powder in fresh sterile distilled water 10 c.c. for each 0.1 Gm of acid arsphenamine. The solution must then be made alkaline by the addition of 0.85 c.c. of a normal (4 per cent) solution of sodium hydroxide for each 0.1 Gm of acid arsphenamine. After alkalinization is complete the solution is filtered through sterile gauze and an additional amount of water is added to make a final volume of 20 c.c. of solution for each 0.1 Gm of arsphenamine. It must be allowed to stand for thirty minutes before being used. Solutions should not be allowed to stand more than four hours before use. Injection must be given slowly by gravity. Three to six injections at weekly intervals are generally given. It is important that the patient eat lightly on the day of injection and omit the meal following the injection.

A number of systemic reactions may follow the use of arsphenamine. The intravenous injection of 0.2 Gm or more of unalkalinized acid arsphenamine almost always results in sudden death.

The Jarisch Herxheimer reaction (therapeutic shock) occurs only after the first and not after subsequent injections of arsphenamine. Within a few hours after the drug is given there occurs a chill, a rise in temperature reaching 103° to 104° F, general malaise and aching. The serious focal reactions characteristic of late syphilis have not been reported.

Several reactions following the injection of arsenicals are nonspecific and are due to the use of the intravenous route. Among these are the "tubing" reaction, the "ether" odor and gastrointestinal reactions. The "tubing" reaction is caused by improper preparation of new rubber tubing. It most often consists of fever, vomiting and headache. The "ether" odor occurs only after the use of arsphenamine, neoarsphenamine and Mapharsen. The odor, which is like that of ether or garlic, is due to the presence of the drug in the blood of the nasal mucosa and occurs within a few seconds after the injection. The patient's awareness of the odor may be lessened by having him breathe through the mouth. The gastrointestinal disturbances comprise the most frequent type of reaction after the arsphenamines. Nausea, vomiting, diarrhea, headache and malaise develop within four to twelve hours after treatment and usually last a few hours. These disturbances develop less frequently if patients are cautioned to eat lightly on the day of treatment and to omit the meal following treatment.

Angioneurotic symptoms may develop after the administration of the arsphenamines. The most common of these is the *nitritoid crisis*. The conjunctiva becomes suffused, the patient complains of being hot, of a feeling of oppression in the chest and palpitation. If the injection is not stopped the patient goes into shock with flushing of the skin, cough, vomiting and

than that of framboesia ulcers unless the latter were secondarily infected A history of contact with other cases of tuberculosis may be obtained Definitive diagnosis of lupus vulgaris can be established by biopsy examination and guinea pig inoculation

12 **Scrofuloderma** is a form of tuberculosis in which the skin is involved secondarily by direct extension from lymph nodes or bones The cervical lymph nodes are those most commonly affected becoming enlarged firm and adherent to the overlying skin Over a period of months or years the overlying skin becomes thinned purplish and depressed It then sloughs at one or more points to form ulcers which serve as mouths of sinuses. These extend deep into the diseased tissue and discharge purulent material At this stage the lesion may resemble a framboesia gumma which has broken down Constitutional symptoms are generally slight or lacking The lesions may persist for a year with little or no change occasionally they heal spontaneously with the formation of rough corded cicatrices The initial lymph node involvement is an important clinical point in differentiating this disease from framboesia Laboratory diagnosis can be made by biopsy examination and guinea pig inoculation

13 **Leprosy** in its early and late stages may simulate framboesia The macules of leprosy are usually oval bilateral in distribution and extend peripherally being most common on the lobes of the ears alae nasae forehead eyebrows cheeks and chin Sensory changes generally develop and serve to differentiate these lesions from those of framboesia The subsequent appearance of nodules with induration and thickening of the skin results in the characteristic leonine facies of leprosy The nodules frequently ulcerate Neural involvement results in trophic changes in the skin Atrophy of muscles leads to contractures and deformities with resorption of bone and ulceration of the skin The diagnosis of leprosy can generally be made on clinical grounds Definitive diagnosis is based upon demonstration of the etiologic agent *Mycobacterium leprae* in the skin

TREATMENT

A number of organic arsenical drugs bismuth and penicillin are specific in the treatment of yaws Mercury and potassium iodide separately or combined tartar emetic and carbarsone are considered to be less satisfactory therapeutic agents

Strong (1910) first tried arsphenamine (Salvarsan) in the treatment of human framboesia and reported its marked specificity It has frequently been observed that one injection of an arsenical drug bismuth or penicillin resulted in rapid healing of the primary and secondary lesions of framboesia This has led to the assumption that this disease is easy to cure However in those few instances where adequate post treatment clinical and serologic observations have been made it has been found that the majority of these patients relapsed frequently and never attained seronegativity

Pertinent information concerning the use of some of the above mentioned drugs in the treatment of framboesia is given below

incidence is highest following neoarsphenamine and seldom if ever occurs after Mapharsen Jaundice appears at variable intervals after treatment ranging from a day to many months It closely resembles infectious hepatitis that is a day or two of malaise slight fever generalized aching epigastric distress anorexia nausea and occasional vomiting followed in four to eight days by the appearance of rapidly deepening jaundice of the *obstructive type* As the jaundice develops the symptoms often disappear The liver becomes enlarged and slightly tender Bile appears in the urine and disappears from the stools Rarely there develop signs and symptoms of acute yellow atrophy intractable vomiting mental dullness apathy drowsiness coma convulsions and death within seven to fourteen days The mechanism of postarsphenamine jaundice is uncertain possibly being due to the direct toxic effect of the arsenicals on the liver Treatment is symptomatic Daily intravenous injections of calcium gluconate (10 c c of 10 per cent solution) appear to accelerate symptomatic improvement

Neoarsphenamine (Neosalvarsan)

Neoarsphenamine (Neosalvarsan) is sodium 3 3′ diamino-4 4′ dihydroxy arsenobenzene N methanol sulfoxylate a derivative of arsphenamine containing 19 to 22 per cent of arsenic in the trivalent form It is given intravenously *in doses equivalent to 0 015 Gm per kilogram of body weight The average* single therapeutic dose is 0 75 to 0 9 Gm for men and 0 6 to 0 75 Gm for women The drug is prepared by dissolving the powder in fresh distilled water using from 2 to 10 c c per 0 1 Gm of drugs A total volume of 15 to 20 c c is usually employed for the average treatment It is not necessary to alkalinize the solution as must be done when preparing arsphenamine The drug must not be allowed to stand longer than twenty minutes Injection is made slowly by syringe at the rate of not more than 0 1 Gm per 30 seconds As in the case of arsphenamine three to six injections at weekly intervals are generally given

Solutions of neoarsphenamine are considerably easier to prepare and administer than those of arsphenamine It causes fewer gastrointestinal reactions is less irritant when accidentally injected into tissues and does not thrombose veins Its chief disadvantage is its instability The ampules must be kept in the dark and on ice if possible and must not be over six months old

Sulfarsphenamine

Sulfarsphenamine is disodium 3 3′ diamino 4 4 dihydroxyarsenobenzene N dimethylenesulfonate a formaldehyde sulfoxylate derivative of arsphenamine containing 19 per cent of trivalent arsenic It is administered intramuscularly in doses equivalent to 0 010 to 0 025 Gm per kilogram of body weight The average single therapeutic dose is 0 6 Gm for men and 0 4 Gm for women The drug is prepared by adding fresh distilled water to the ampule 0 3 c c per 0 1 Gm of drug Solution should occur quickly and com

severe back pain Occasionally there develops swelling of the face, lips, tongue, or eyelids, and generalized urticaria The patient experiences fear of impending death, and the reaction may sometimes be fatal However, the symptoms usually disappear in twenty to sixty minutes without residual effects and even without treatment It is safer to treat the patient by intramuscular injection of 0 5 to 1 0 c c of a 0 1 per cent epinephrine hydrochloride solution The incidence of this reaction is about 0 1 per cent of all injections of arsphenamine and neoarsphenamine but has not been reported after Mapharsen The cause is not known Rapid injection is undoubtedly the major factor in most cases

Acute heart failure may result when an arsphenamine is administered to a patient with myocardial damage from cardiovascular syphilis Thus, heart disease of any nature is a contraindication to the use of the arsphenamines

The arsphenamines are capable of producing a wide variety of toxic manifestations in the skin ranging from minor dermatitides to grave and sometimes fatal exfoliative dermatitis The distribution may be widespread or localized as in the case of herpetiform and fixed arsenical lesions The major dermatitides are due to drug sensitization and nearly always necessitate abandonment of arsenical treatment The interval between treatment and the appearance of the rash is about five days on the average It begins usually as a maculopapular or vesicular dermatitis, often limited at first to the extremities, but rapidly spreading over the whole body Erythema may be generalized and itching is severe In the milder cases the process may stop here, and the eruption disappears in a few days In the more severe cases, marked scaling and exfoliation occurs and the skin of the entire body is desquamated in large flakes Marked constitutional symptoms and evidence of visceral damage may be associated with the eruption Fever, malaise, and prostration are common, jaundice albuminuria hematuria, and polyneuritis are relatively infrequent complications The patient should be hospitalized and treated symptomatically Intravenous glucose (500 c c of 5 per cent solution) and calcium gluconate (10 c c of 10 per cent solution) should be given daily Large amounts of vitamin C (0 500 Gm) daily may be beneficial The incidence of the dermatitides varies from 0 5 to 14 per cent of all injections of arsphenamines being highest following sulfarsphenamine and lowest after Mapharsen injections

Among the reactions from arsphenamines in the central nervous system are polyneuritis hemorrhagic encephalitis transverse myelitis, and ocular damage These occur infrequently and usually only after a large number of injections have been made

Blood dyscrasias due to the arsenical drugs are relatively rare Three types of reaction are recognized thrombocytopenia, granulocytopenia, and aplastic anemia These are among the most serious of arsenical treatment complications, having a high mortality rate

Postarsphenamine jaundice is a fairly frequent complication of arsphenamine therapy, occurring in approximately 0 02 per cent of all injections The

week's rest the course of treatment is repeated. Its chief advantage is that it can be given orally, but this is outweighed by its toxicity and the poor results obtained with it. The full course of treatment with acetarsone may be more expensive than that of neoarsphenamine or Mapharsen.

Bismuth

Bismuth is available in a confusing number of preparations. The metallic bismuth content of these varies so that it is necessary to acquaint oneself with the preparation being used. Some of those commonly used are as follows:

a. **Bismuth subsalicylate** is an insoluble preparation made up of a 10 per cent suspension of basic bismuth salicylate in olive or peanut oil. It contains *0.057 Gm. of metallic bismuth per cubic centimeter of drug solution.* *Three* to six intramuscular injections of 1 or 2 c.c. (0.1 or 0.2 Gm.) at weekly intervals are recommended.

b. **Potassium bismuth tartrate** is another insoluble preparation made up of a 10 per cent suspension of basic bismuth potassium bismuthotartrate in peanut oil with 0.4 per cent of butyn. The dosage is the same as that of bismuth subsalicylate.

c. **Bismosol** is a soluble preparation of potassium sodium bismuthotartrate in 10 per cent glucose solution. It contains 0.035 Gm. of metallic bismuth per cubic centimeter of solution. It is administered intramuscularly twice or three times weekly for two or three weeks in doses of 1 c.c. (0.1 Gm.) each.

d. ***Thio-bismol*** *is another soluble preparation of sodium bismuth thioglycollate.* 0.2 Gm. is dissolved in 1 c.c. of distilled water. It contains 0.076 Gm. of metallic bismuth per cubic centimeter of solution. The dosage is the same as that of bismosol.

Toxic effects occur rarely if an acceptable bismuth compound is given properly by the intramuscular route. Injection of 1 c.c. of air into the muscle before withdrawing the needle and routine massage are two ways of decreasing the discomfort attending treatment. Large numbers of injections of insoluble bismuth have been given with no untoward local effect. Sterile abscesses and sclerosing myositis are seen infrequently. The accidental injection of bismuth into a vein may cause oil embolism of the lungs which may be fatal. Arterial embolism results in painful induration of the buttock. The insertion of the needle before syringe is attached and retraction of the plunger for several seconds to see whether blood can be aspirated are precautions to be taken in order to prevent accidents.

Certain systemic reactions may occur following the administration of bismuth. Pigmentation of the gum margins and buccal mucosa is frequently seen after six or more injections. It persists for years but has no serious significance. Ulcerative stomatitis calls for immediate cessation of bismuth therapy. Jaundice, nephritis and dermatitis are uncommon. At times gastrointestinal disturbances, malaise, fever, headache and pains in the joints and bones develop after each injection and may be serious enough to necessitate cessation of the drug.

pletely Solutions should not be permitted to stand more than three or four hours Here again three to six injections at weekly intervals are generally given

Sulfarsphenamine is the only arsphenamine well tolerated by intramuscular injection It is most useful in the treatment of infants and children as well as in some obese patients and others with inaccessible veins It is stable in solution and in the ampule Immediate reactions are less common than with the other arsenicals but the incidence of serious late reactions in adults is so high that sulfarsphenamine should not be employed if it is possible to use one of the other arsenicals intravenously Fortunately infants appear to be less susceptible to the untoward effects of the drug and for them it is probably the drug of choice at present

Mapharsen (Mapharside)

Mapharsen (Arsenoxide) is 3 amino 4 hydroxyphenylarsinoxide hydrochloride representing a partial oxidation product of arsphenamine It contains 29 per cent of trivalent arsenic It is administered intravenously in doses equivalent to 0 0010 Gm per kilogram of body weight which is one tenth that of arsphenamine The average single therapeutic dose is 0 06 Gm for men and 0 04 Gm for women The drug is prepared by dissolving the powder in fresh sterile distilled water using 2 to 3 c c per 0 01 Gm of drug Solution occurs quickly with effervescence Stirring to insure solution is permissible and desirable Aeration and exposure for hours does not increase the toxicity or decrease the therapeutic value of the solution A brown color may appear after prolonged standing but this is of no importance Injection is made rapidly by syringe giving the entire dose within fifteen to thirty seconds This lessens pain in the arm and decreases the possibility of thrombosis from vascular irritation Three to six injections at weekly intervals are usually given

Mapharsen has a number of advantages over the arsphenamines It is easy to administer requiring no special precautions in preparation It can be given by syringe and can be injected rapidly as soon as the solution is made Large amounts of solution may be prepared for mass treatment in the clinic because the solution keeps for hours It is a pure chemical substance which is uniform in constitution and can be chemically as well as biologically standardized The dose of Mapharsen is much smaller than that for arsphenamines so that less arsenic need be handled by the body Gastrointestinal upsets dermatitides and visceral reactions are less frequent Nitritoid reactions do not occur Excretion appears to be more rapid than that of the arsphenamines so that Mapharsen can be given twice weekly for two or three weeks

Acetarsone (Stovarsol)

Acetarsone (Stovarsol) is acetylamino hydroxyphenylarsonic acid It is a synthetic pentavalent arsenical which may be administered by mouth The drug is supplied in tablets containing 0 05 0 25 and 0 1 Gm The dose for adults is 0 25 Gm three times daily for seven days After a

With regard to the effect of treatment on the blood only a few extensive studies have been reported Goodpasture and de Leon (1923) found that the Wassermann test which was strongly positive before treatment gradually weakened and became negative in seven cases within six months after treatment Chambers saw reduction of seropositivity Dwinelle Rein Sternberg and Sheldon reported that approximately 98 per cent of the patients who had received 1 200 000 units of penicillin in aqueous solution over a four day period showed definite evidence of reduction in Kahn titer three months after treatment

PROPHYLAXIS AND CONTROL

The avoidance of direct and indirect contact with an infectious case of framboesia is an obvious preventive measure Isolation and treatment of such cases should be carried out if possible Infected children should not be allowed to attend school When feasible the lesions should be covered with a clean dressing The wearing of shoes stockings and trousers will prevent trauma of the skin of the extremities Cuts or abrasions may be treated locally with mercury ointment The liberal use of soap and water is an important prophylactic weapon but this is usually beyond the economic and physical means of natives in highly endemic countries Mass treatments regularly and continuously in these areas appear to be the only approach to control To be successful adequate organization health education sufficient funds and trained personnel are needed The development of a satisfactory one treatment drug would be a valuable contribution Penicillin in oil beeswax or a similar preparation holds promise in this respect

Goodpast sserman

The insoluble bismuth preparations appear to hold preference over the soluble preparations in the treatment of framboesia Bismuth is easier and more economical to administer than the arsphenamines and is safer for aged and weak patients It may be used to advantage in combination with the arsphenamines or Mapharsen

Penicillin

Penicillin is the most recent addition to the specific therapy of framboesia It may be administered intravenously or intramuscularly The dosage has not been definitely established but it seems likely that it should approach that employed at present for syphilis namely 2 400 000 Oxford Units or more However there are reports in the literature of the use of as little as 10 000 U Dwinelle Rein Sternberg and Sheldon (1946) treated 500 patients in Haiti with total doses of 1 200 000 Oxford Units for adults The patients were divided into three approximately equal groups One group was hospitalized and each patient regardless of age was given thirty intramuscular injections of 40 000 Oxford Units of penicillin sodium in aqueous solution every three hours day and night The second group was treated on a two day ambulatory basis in a clinic Each adult patient received two injections of 600 000 Oxford Units of penicillin calcium in peanut oil with 4 8 per cent beeswax by weight (300 000 U per cubic centimeter) twenty four hours apart The dosage in this and the subsequent group was graded down for children those 6 to 12 years of age received a total of 600 000 Oxford Units and those 13 to 16 years received a total of 900 000 U The last group was treated on a one day *ambulatory basis the adults receiving two injections of 600 000 Oxford Units* of penicillin calcium in peanut oil with beeswax ten to twelve hours apart No severe toxic reactions were encountered Approximately one half of the hospitalized patients were observed to have a rise in temperature of 100° to 104° F two to eight hours after treatment was started All temperatures gradually returned to normal in ten to twelve hours

The response of framboesia lesions to regular arsphenamine Mapharsen bismuth or penicillin therapy is rapid and remarkable Healing of most primary and secondary skin lesions is usually complete within a week unless extensive secondary bacterial infection is present Bone lesions heal readily if treated early Crab lesions and tertiary stage ulcers respond slowly to treatment Gangosa and goundou may be arrested only temporarily showing little or no improvement

Infectious relapsing lesions occur more frequently during the first year following treatment than in the second year Chambers (1938) reported that the percentage of relapses of cases receiving four or more treatments was less than of cases receiving three or less whether treatment was with neoarsphenamine or with bismuth salicylate Figures for the incidence of relapses after Mapharsen therapy are not available at present A large number of patients have been treated with Mapharsen in Haiti with excellent clinical results Dwinelle Rein Sternberg and Sheldon (1946) reported a relapse rate of less than 1 per cent within six months after treatment with penicillin

CHAPTER 17

THE VIRUSES AND VIRUS DISEASES OF MAN—GENERAL CONSIDERATIONS

S EDWARD SULKIN

The study of viruses has grown during the last thirty years from an obscure and little known subject into an important branch of medical science. Although viruses have been known to exist for more than half a century their small size has precluded truly scientific study until recent years when viruses and the diseases due to them have been studied extensively. When viruses first became known a tendency arose to assign viral etiology to any disease the causal agent of which was in question but during the past two decades the subject has developed precision and the list of known virus diseases has begun to be differentiated. Advances have been so rapid and contributions to our knowledge so varied and numerous that only the major discoveries can be considered in this discussion.

The virus diseases which are encountered in practically all specialties within the field of medicine vary in their clinical and epidemiologic manifestations in the same manner as bacterial infections. Certain viruses cause disease of the central nervous system, others affect the eye while still others may produce cutaneous lesions. The respiratory diseases caused by viruses are among the most common ailments and numerous tropical diseases fall within this category.

THE NATURE OF VIRUSES

Much of the information concerning the nature of viruses has been obtained through the use of high speed analytical centrifuges by x ray analysis by filtration through graded collodion membranes and through the use of electron microscopy. Measurements of the tobacco mosaic virus have been made possible through the discovery of a method of separating the virus in purified and crystalline form. The tobacco mosaic virus has now been studied extensively and provides a standard scale of size by which all viruses are measured. The particle size of many of the large viruses such as those of psittacosis and trachoma has been determined by direct visual observation while those too small to be resolved with ordinary light have been measured by photography with ultraviolet light or with the electron microscope. The molecules of tobacco mosaic virus as revealed by the electron microscope appear as pencil like structures while those of the virus of equine encephalo*myelitis seem to be circular in shape and uniform in size.* Electron microscope studies of the elementary bodies of the vaccinia virus reveal rectangular particles of uniform size in which can be seen areas of concentration somewhat darker than the surrounding material.

droplet infection the virus reaching the central nervous system from the nasal mucosa by traveling along the olfactory nerve Recent studies of the pathogenesis and pathology of poliomyelitis however would indicate that portals of entry other than the nasopharynx exist in the human disease Lesions in the olfactory bulbs which occur when the disease is produced experimentally in the monkey by instilling the virus into the nose are uncommon in human poliomyelitis Evidence suggests that the alimentary tract is the usual portal of entry of the virus Supporting this view are the observations concerning the persistence of virus in stools of convalescents presence of virus in stools of healthy contacts and spread of the disease by healthy carriers and by flies Whatever the portal of entry virus may be recovered from the intestinal tract more easily than from the nasopharynx

Numerous studies have been undertaken to determine the mode of transmission of the virus encephalitides Several investigators suggested the possibility of mosquito transmission in St Louis encephalitis and the experimental transmission of the Western equine virus with *Aedes aegypti* (Kelser 1933) indicated a similar mode of spread in equine encephalomyelitis Studies conducted at the Hooper Foundation of the University of California (Hammon and Reeves 1945 Howitt and van Herick 1942) have shown that both of these viruses are endemic in certain areas and that the sera of many mammals and birds contain neutralizing antibodies to these viruses Hammon et al (1942) isolated several strains of the St Louis virus and the Western equine virus from a single species of mosquito (*Culex tarsalis* Coquillet) and found that this mosquito was capable of transmitting these viruses under experimental conditions (Hammon et al 1942a) Other species of mosquitoes have subsequently been added to the list of possible vectors (Hammon Reeves and Gray 1943) It is possible that arthropods other than the mosquito might be capable of transmitting these diseases Supporting this idea is the observation by Blattner and Heys (1943) that experimentally infected dog ticks (*Dermacentor variabilis* Say) are capable of transmitting the disease Smith Blattner and Heys (1944) also reported isolation of St Louis encephalitis virus from chicken mites (*Dermanyssus gallinae)* and showed that mites infected in nature retained the virus after five months of propagation in the laboratory Congenital transfer of the virus from the adult female through the egg into the first stage nymph could be affected (Smith Blattner and Heys 1945)

In 1948 Smith et al presented a concept of the epidemiology of St Louis encephalitis based on well documented experimental evidence They suggest that two blood sucking vectors may be involved one an arachnid the mite which maintains the virus in nature by transovarian passage the other an insect the mosquito which carries the virus from birds to other vertebrates including man Because of the similarity in the natural history of equine encephalomyelitis to that of St Louis encephalitis it is likely that the same factors might be involved in the epidemiology of equine encephalomyelitis This concept is supported by the fact that the Western equine virus was isolated from chicken mites *Dermanyssus gallinae,* in nature by the author during the course

Many of the early workers regarded viruses as minute microbes which simply could not be resolved by means of ordinary light. These agents possess the ability to multiply when introduced into living cells. In fact there is direct microscopic evidence that at least some of the larger viruses (e.g. elementary bodies of vaccinia) multiply by binary fission just as do bacteria. The ability to proliferate and become adapted to changes in environmental conditions is a property of the living organism distinguishing it from inanimate matter. For this reason Green (1935) suggested that viruses might be regarded as bacteria which have lost certain enzyme systems and being obligate parasites are dependent on the metabolism of the host cell for specialized functions other than reproduction. Some workers on the other hand have suggested that they might be nonliving autocatalytic enzyme-like agents since they cannot be cultivated apart from living cells. Supporting this view was the report by Stanley (1935) of the successful isolation of a crystalline protein possessing the properties of the tobacco mosaic virus. No conclusion can as yet be drawn regarding the true nature of the viruses though the observations of Stanley have given new impetus to this field of investigation.

Certain species of microorganisms (e.g. Salmonella group) have been found to contain seven or eight separate antigens which make up the antigenic mosaic of the cell. A similar situation obtains with many viruses and the antigenic complexity may be indicated by the antibodies produced. In many instances one type of antibody is elicited by the virus and the other is produced by the soluble antigen which is separable from the virus. The virus apparently gives rise to the so-called neutralizing antibodies while the soluble antigens produce antibodies which can be demonstrated by the classical precipitation, agglutination or complement fixation tests. Not long ago Smadel, Ward and Rivers (1940) found that the soluble antigen of infectious myxoma of rabbits contained two immunologically distinct components which could be separated by certain physical methods. Vaccinia virus has been shown to have at least five antibodies demonstrable in animals which recover from infection with this agent (Smadel and Hoagland 1942). Other viruses appear to be more simple; for example in poliomyelitis the only humoral antibody which can be demonstrated is one which neutralizes the virus, and tobacco mosaic and rabbit papilloma produce complement fixing and neutralizing antibodies which react with a single antigen.

EPIDEMIOLOGY

Much information has been accumulating concerning our understanding of the mode of transmission of certain diseases of viral origin. But the problem is far from solved at this time. For example the true epidemiology of poliomyelitis is not yet clearly understood. It appears certain that many factors involving environmental temperature, presence of insects and possibility of an extrahuman reservoir of the virus must be considered. For many years it was thought that poliomyelitis was a contact disease spread by

The epidemiology of many of the other virus diseases is equally perplexing. One of the greatest mysteries of epidemiology is what happens to a virus between epidemics and what causes it to reappear from its quiescent state. An important step toward the solution of this problem was made by Shope (1943) when he noted that swine lungworms (*Metastrongylus elongatus* and *Choerostrongylus pudendotectus*) nematodes parasitic in the bronchioles of the lungs of swine were capable of harboring swine influenza virus and of transmitting it from animal to animal. Complicating this apparently simple mode of transmission is the fact that the lungworm has an intermediate host of its own. Fig. 132 indicates diagrammatically the life cycle of the swine lungworm and represents the author's interpretation of Shope's studies concerning the swine lungworm as a reservoir and intermediate host for swine influenza virus. The virus apparently persists in the lungworm in a noninfective form from which it can be provoked into activity by appropriate stimuli (intramuscular injections of *Hemophilus influenzae suis*). The fact that noninfective virus is able to survive for at least two years in the lungworm larvae in the earthworm and, in addition, for several months in the swine respiratory tract would explain survival of the virus between epidemics. Furthermore Shope (1943) observed that transmission of swine influenza virus by lungworms takes place only if experiments are conducted during the fall and winter months, which fits well with the seasonal incidence of swine influenza. What causes fully active swine influenza virus to become noninfective when taken up by the lungworm *and to resume its infectivity when it again finds itself* within a susceptible host is still unknown. These observations, probably the most important in the field of virology in recent years, suggest that a similar cycle might operate in many virus diseases of the human being. In recent studies Syverton et al. (1947) showed that the parasitic nematode *Trichinella spiralis* can serve as a vehicle for the experimental transmission of lymphocytic choriomeningitis virus from one host to the next. These observations may have practical implication in the epidemiology of human lymphocytic choriomeningitis.

DIAGNOSIS

The diagnosis of certain diseases of viral origin may be confused by their frequent association with other infectious processes of similar clinical manifestations. For example, influenza during the acute phase may be accompanied by infectious "colds," and later may be complicated by pneumonia or central nervous system involvement. Also encephalitis may complicate such diseases as smallpox, measles, mumps, chicken pox, and whooping cough. The study of virus diseases is rendered more difficult by the interrelationship of these maladies with other infections, both bacterial and viral. In recent years correlated clinical, laboratory, and epidemiologic studies have permitted investigators to dissociate certain virus diseases which present similar clinical manifestations and to establish well-defined criteria for determining their identity.

of an outbreak in horses (Sulkin 1945) * Also, this virus has been recovered from bird mites by Reeves et al (1947), Hammon et al (1948), and by Sulkin and Izumi (1945) Laboratory transmission experiments with the view of demonstrating transovarian infection in mites are now in progress in this laboratory Evidence is also conclusive that reservoirs of the equine virus exist in wild and domestic animals including birds For a review of recent advances in the epidemiology of the arthropod borne virus encephalitides the reader is referred to the excellent article by Hammon (1948)

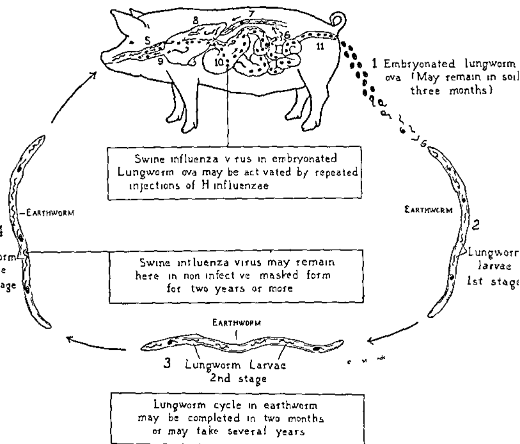

Fig 132—The swine lungworm as a reservoir and intermediate host for swine influenza virus (Shope)
Embryonated eggs which are laid by the adult female lungworm in the bronchi of the swine are coughed up swallowed and then eliminated in the feces 1 Upon ingestion by earthworms the lungworm eggs pass through developmental cycles 2 3 until the third larval ... e lungworm larvae is then eaten ... by way of the blood stream and ... mbryonated lungworm eggs which ... 9 swallowed 10 and eliminated ... 240 1944 by permission of the publisher)

*Since this manuscript was submitted for publication Howitt and her associates (1949) reported isolation of the virus of Eastern equine encephalomyelitis from chicken mites (*Dermanyssus gallinae*) and chicken lice (*Eomenacanthus stramineus*)

have been prepared by means of ultraviolet light irradiation and such antigens can be lyophilized and kept for long periods of time Only recently Casals (1945) described a simple method for producing avirulent mouse brain antigen for complement fixation tests by the application of heat at 60° C for thirty minutes The heated antigens retained a sufficiently high titer to warrant their use

Because of the increased interest in the development of complement fixing antigens derived from chick embryo and mouse brain tissues Cox (1948) and associates undertook development of antigens free from nonspecific factors They found that such antigens for a variety of neurotropic viruses could be prepared without appreciable loss in antigenicity by extraction in the desiccated state with benzene Such antigens are rapidly becoming available commercially In addition to its use with the virus encephalitides the complement fixation test has been found to be of practical value in the diagnosis of a number of other diseases of viral etiology including influenza lymphogranuloma venereum yellow fever and mumps The test appears to be of particular value in the diagnosis of those cases of acute aseptic meningoencephalitis in which previous involvement of the salivary glands was inapparent (Kane and Enders 1945)

Other developments in the field of virology have simplified procedures used in the diagnosis of this group of diseases For example the necessity for using bacteriologically sterile material in virus study has been largely overcome by the use of ether Zephiran the antibiotics and sulfonamide compounds to rid specimens of bacterial contaminants The use of bactericidal agents obviates the need for filtration which is frequently unsatisfactory because the viral agent may itself be retained along with the undesirable bacteria A number of reports have appeared in the literature concerning the usefulness of these bactericidal agents Ether may be used to destroy bacterial contaminants without affecting the poliomyelitis rabies or measles viruses Zephiran has been found satisfactory for the isolation of the influenza virus from throat washings With a few possible exceptions the growth of viruses in living hosts appears to be unaffected in the presence of a wide variety of antibiotics Reference has been made to the isolation of the herpes virus by primary inoculation of unfiltered sputums treated with penicillin (Rose et al 1945) The isolation of the mumps virus directly from human saliva by inoculation with penicillin into the amniotic cavity has also been reported (Beveridge Lind and Anderson 1946) Streptomycin and tyrothrycin were found useful in the isolation of psittacosis virus from fecal material by direct injection into the yolk sac of developing chick embryos (Morgan 1947a) The sulfonamides alone and in combination with antibiotics have proved useful in eliminating bacterial contaminants from specimens examined for various viruses

The discovery by Hirst (1941), and independently by McClelland and Hare (1941) that influenza virus possesses the capacity to agglutinate erythrocytes provided a valuable new approach to the study of viral agents The so called hemagglutination test is now widely used in the diagnosis of epidemic influenza and the antigenic pattern of strains of influenza isolated during different epidemics has been compared by means of this technic It is now

The procedures followed in the laboratory diagnosis of diseases caused by viruses are analogous to those used in bacterial infections. Conclusive evidence consists in the demonstration and identification of the virus. This may be accomplished in some of the virus diseases by using susceptible laboratory animals or chick embryos instead of the ordinary culture media used for the isolation of bacteria. Once the virus is recovered, identification is accomplished by determination of the animals for which it is pathogenic, routes by which it can be injected, tissues it infects, lesions produced, and through the use of the classical immunologic reactions, i.e., neutralization, complement fixation, agglutination, or precipitation reactions. The most conclusive evidence is available when virus has been recovered from a patient and an increase in neutralizing or complement fixing antibodies demonstrated in the convalescent serum of the same individual; nevertheless, laboratory studies have indicated that serologic procedures alone are valuable even in the absence of virus recovery. When it is not feasible to attempt recovery of virus from tissues, immunologic tests should be carried out using the blood serum obtained during the early stages of the disease and again after recovery of the patient. The presence of specific antibodies is of particular significance if blood specimens taken during the acute phase are negative and become positive with convalescence of the individual.

The clinical syndrome produced by some viruses is quite consistent, permitting the physician to make a proper diagnosis without resorting to laboratory aids. Typical of such diseases are measles, chickenpox, and smallpox. Again, some virus diseases cannot be differentiated until an etiologic diagnosis has been made and the causative agent has been identified by means of laboratory procedures. Thus, for example, the clinical, pathologic, and epidemiologic manifestations of the neurotropic virus diseases (excluding poliomyelitis and rabies) are so alike that it is practically impossible to establish the identity of a particular disease without the aid of laboratory studies. The "infectious encephalitides," embracing a number of distinct diseases of the central nervous system, must be identified etiologically if reliable epidemiologic data are to be obtained and if this group of diseases is to be properly classified. Knowledge concerning the "virus encephalitides" would be greatly enhanced if physicians made an earnest effort to secure laboratory aid for the identification of the causative virus.

Much work has been done in recent years to simplify laboratory procedures and attention has been directed toward the use of the complement fixation test for the diagnosis of the human virus encephalitides. The test described by Casals and Palacios (1941) and by Havens et al. (1943) is sufficiently specific to differentiate the various experimental infections caused by the neurotropic viruses. This test has already yielded encouraging results when used in the diagnosis of human infections induced by some of these viruses (Casals, 1947; Sulkin and Izumi, 1945). Because of the dangers inherent in the use of virulent antigens in these tests, attempts have been made to inactivate them without altering the efficacy of the material (Sulkin and Pike, 1949). Avirulent antigens

amount of protection is afforded by inactive viruses (equine encephalomyelitis, influenza, rabies and others). To be sure, immunity conferred with inactive agents is of short duration and vaccination should be repeated at frequent intervals.

In recent years efforts have been directed toward the development of prophylactic measures against various diseases through the use of attenuated and inactivated viruses. Epidemic influenza has received special attention. Various vaccines have been given parenterally while others have been given intranasally. The formalinized complex influenza A canine distemper vaccine of Horsfall and Lennette (1940) which received extensive clinical trial has been superseded by an influenza type A and B vaccine developed by wartime research. This vaccine which is now available for civilian use is effective in providing protection against the type A and B influenza viruses which have been the most prevalent causes of epidemics in recent years (Francis et al 1947). This vaccine contains influenza virus concentrated from allantoic fluid of developing chick embryos by adsorption on and elution from embryonic erythrocytes. During the winter of 1943-1944 extensive investigations of the prophylactic effect of influenza vaccination were carried out under the auspices of the Commission on Influenza of the Army Epidemiological Board. These studies indicate that subcutaneous vaccination of a human population with the newly described vaccine exerts a definite effect on the susceptibility to influenza A during an epidemic of high incidence (Francis 1945).

A number of investigators have emphasized that possible untoward reactions may be due to allergenic and anaphylactogenic properties of vaccines prepared from embryonic tissues of developing chicks. It has recently been suggested that intradermal injection of small doses of vaccine may obviate these difficulties. Van Gelder et al (1947) recently compared the rise in antihemagglutinins following intradermal and subcutaneous inoculation of concentrated vaccine prepared from strains of A and B influenza viruses. The intradermal dose which was about one tenth the subcutaneous dose induced a greater mean antibody response and the incidence of generalized reactions was lower in the group which received intradermal inoculations. Similar findings were recently reported by Weller et al (1948). Actually the prophylactic value of intradermal vaccination has not as yet been demonstrated.

Little attention has been given to the problem of passive immunity because of the transient nature of the protection conferred. Passive immunity can be produced experimentally, however, by intranasal instillation of small amounts of immune serum prior to inoculation with influenza virus. Russian investigators (Smorodintseff et al 1940) reported startling results following biweekly inhalations of vaporized antiserum given to a large number of individuals before and during an epidemic of influenza A. These observations were subsequently confirmed by Krueger et al (1944) who investigated the efficacy of this procedure in the prophylaxis and therapy of experimental influenza.

known that other agents including those of vaccinia variola fowlpox New castle disease ectromelia of mice mumps pneumonia virus of mice and pleuro pneumonia like organisms cause specific agglutination of erythrocytes With all of these agents the agglutination of erythrocytes may be inhibited by the addition of specific immune serum for this reason the reaction has already been widely applied to various aspects of virus research Recently two strains of mumps virus have been isolated directly from human penicillin treated saliva by inoculation into the amniotic cavity of the chick embryo and hemagglutinin was detected after three to four days incubation (Beveridge Lind and Anderson 1946) It has been suggested that the hemagglutination test with this virus may provide a more rapid and convenient diagnostic method for detecting increases in antibody concentration than other serologic procedures

Skin sensitivity tests are being developed which may prove valuable in the diagnosis of viral diseases A cutaneous sensitivity test is of particular value under circumstances where facilities for examining serum for specific antibodies are not readily available Such tests have been described for vaccinia and lymphogranuloma venereum but the latter is the only viral disease in which a skin test the Frei intradermal test is now widely employed as a diagnostic aid With improved methods for growing viruses in high titer there is reason to believe that intradermal reactions will be employed with increasing frequency In recent years a number of other intradermal tests with antigens of viral origin have been introduced Nagler (1944) and more recently Rose and Molloy (1947) reported specific dermal reactions in herpetic persons receiving intracutaneous injection of heat inactivated herpes virus cultivated in the chick embryo Since a positive reaction could be correlated with the presence of circulating antibody this test may eventually be of value in differential diagnosis Influenza virus produces a cutaneous reaction in most adults and in some children and it is possible according to Beveridge and Burnet (1944) that allergy to the virus may play a part in resistance to infection Whether or not this reaction will be useful in determining susceptibility to influenza remains to be seen A dermal sensitivity test for mumps using parotid glands of infected monkeys as antigen may be of value in the diagnosis of this disease It has been shown that persons exhibiting erythematous dermal reactions forty eight hours after inoculation of this material may be from the practical standpoint considered resistant to mumps (Enders et al 1946) Dermal sensitivity tests will undoubtedly be further investigated because of their potential importance as diagnostic procedures

Recommended laboratory procedures have been summarized by several investigators (Sulkin and Harford 1943 Sulkin 1943 Francis et al 1948 van Rooyen and Rhodes 1948)

PROPHYLAXIS

Earlier workers believed that artificial immunity could not be induced unless active virus was used in preparing the vaccines While this may be true in the case of some viruses it appears that in many cases a considerable

and highly antigenic but should contain several different strains of polio myelitis virus Extensive study in animals suggest promising results (Morgan et al , 1947)

Encouraging results with rabies and St Louis encephalitis viruses were also reported by Levinson et al (1945) with a vaccine similar to that just described (Milzer et al 1945) Several lots of rabies vaccine inactivated by this irradiation technic consistently induced a higher degree of immunity in mice than control phenolized vaccine The irradiated rabies vaccine showed no significant loss of potency after six months' storage at 5° C Similarly two lots of St Louis encephalitis vaccine inactivated by irradiation conferred a high degree of immunity in mice These reports are of a preliminary nature and the results cannot be evaluated until more extensive studies are available*

Sabin and Schlesinger (1945) reported the production of immunity to dengue fever with virus modified by propagation in mice These investigators observed that beginning with the seventh passage in mice the virus had undergone extensive modification in its pathogenic properties Human volunteers who were inoculated with the seventh ninth or tenth mouse passage dengue virus either alone or in combination with yellow fever vaccine were found to be immune when they were exposed to the bite of *Aedes aegypti* mosquitoes of proved infectivity Other volunteers who served as controls developed typically severe unmodified dengue

TREATMENT

A rational approach to research on the treatment of virus infections presents numerous difficulties because of the nature of the virus itself These agents multiply intracellularly and little is known regarding the mechanism of their pathogenesis Furthermore since viruses lack independent enzyme systems their metabolism must be intimately associated with that of the host cell Their only attribute of life appears to be their ability to reproduce and even here the energy of the host cell is necessary It is not therefore surprising that they have proved refractory to the antibiotic sulfonamide and other chemotherapeutic agents which have been so effective in combating other agents of disease On the basis of our present knowledge regarding these simpler forms of life the most promising method of attack with drugs would be that directed toward the reproductive process It is probable that the virus after gaining access to susceptible tissues of the host stimulates the cell in such a way that it is diverted from its normal function to that of synthesizing the virus complex Since these synthetic processes are presumed to be catalyzed by enzymes virus reproduction may be inhibited by the phenomenon of drug enzyme substrate competition

Sulfonamide therapy has proved successful in trachoma inclusion blennorrhea and lymphogranuloma venereum though there is increasing evidence that the causative agents of these diseases do not fall within the category

*Editor's note (O F) The Lederle Laboratories have recently developed an avian rabies vaccine which is very promising

For several years a living neurotropic strain of virus was used in vaccination against yellow fever Because of the pathogenicity of this virus for the nervous system vaccination of the human being was accompanied by adequate protecting doses of immune serum The development of a strain of virus attenuated by prolonged cultivation in vitro led to the production of a relatively safe vaccine which does not require the concomitant administration of immune serum The effectiveness of this vaccine which has been used extensively since 1937 has been indicated by the demonstration of protective antibodies in vaccinated persons and by the curtailment of epidemics of jungle yellow fever (Bugher and Gast Galvis 1944)

The need for an effective type of vaccination of man against the viruses of equine encephalomyelitis became apparent when reports appeared of the occurrence of human infection under natural conditions and laboratory infection resulting from exposure to the virus (Sulkin and Pike 1949) Beard et al (1940) vaccinated a group of laboratory workers with a formalin treated chick embryo vaccine prepared with Eastern and Western strains of equine encephalomyelitis No instance of infection by these agents has been observed in the vaccinated group These observations are significant in view of the high incidence of infection among laboratory workers with the Eastern or Western types or with the Venezuelan type of equine encephalomyelitis (Sulkin and Pike 1949) According to Beard et al (1941) the immunity induced in man by formalin treated vaccine is of a temporary nature requiring revaccination of those continually exposed to infection Immunity in horses resulting from actual infection is enduring in contrast to the immunity induced by injections of chemically treated vaccine (Cox and Olitsky 1936)

Not long ago Sabin (1943) undertook to develop suitable and safe vaccines for protection of human beings against the St Louis and Japanese B types of epidemic encephalitis The resulting vaccines in which the virus has been rendered noninfective by formalin were capable of conferring protection rapidly could retain their potency after storage for long periods of time and produced no ill effects on inoculation in healthy persons The effectiveness of these vaccines must await further trial under natural conditions (Sabin 1947 Warren Smadel and Rasmussen 1948)

Poliomyelitis has been intensively investigated in an effort to find a method of active immunization that will be both effective and safe Inactivated vaccines fail to produce satisfactory protection while vaccines containing active virus though possibly effective may lead to infection A few years ago two large scale experiments on active immunization of human beings were terminated because of this danger In 1945 Milzer et al using the mouse adapted Lansing strain of poliomyelitis virus described a completely inactivated vaccine which confers a high degree of protection against subsequent intracerebral inoculations in mice Since immunologically distinct strains of poliomyelitis virus are known to exist these workers suggest that a vaccine for prophylaxis against human poliomyelitis must not only be safe

In view of the apparent ineffectiveness of the various antibiotics, antisera and sulfonamides in the treatment of virus diseases another approach to the problem is indicated In the light of our knowledge today, treatment of virus diseases in general is largely a matter for future development

of true viruses Scattered reports of successful treatment of other virus diseases have appeared but the observations still require confirmation Apparently, good results with certain therapeutic agents may be due either to mistaken diagnosis or to the beneficial effects of concomitant therapy These criticisms apply to certain studies indicating a favorable effect of the sulfonamides in the treatment of trachoma Favorable experimental results with sulfonamides in the treatment of lymphocytic choriomeningitis have not been consistent when effective they were dependent upon early administration and more nearly approached prophylaxis than treatment Sulfonamide therapy has been given extensive trial in patients with primary atypical pneumonia Neither symptomatic improvement nor alteration in the febrile course was observed with any degree of consistency many patients were even more uncomfortable when receiving the drugs Sufficient evidence exists to conclude that the sulfonamide drugs have no direct effect on infections caused by viruses Secondary infection of the vesicles in smallpox is believed to be responsible for much of the late toxemia in this disease It has been shown (Leishman 1944) that the administration of sulfonamides throughout the course of the infection has strikingly diminished the degree of secondary infection and consequently lessens mortality Penicillin has been observed to have a similar effect (Jeans Jeffrey and Gunders 1944)

Extensive attempts at serotherapy have likewise been unsuccessful in treatment of virus diseases The primary difficulty with serotherapy lies in the fact that viruses are intracellularly situated and the immune bodies cannot reach the infectious agent because they are unable to enter the cell Evidence also indicates that in most virus diseases all cells which are subject to infection have already been invaded by virus by the time symptoms appear Future success in the treatment of virus diseases with immune bodies will depend to a great extent upon the development of methods for earlier diagnosis For each intracellular parasite the appropriate time beyond which parenteral injection of antibodies is no longer effective must be determined experimentally Despite several reports to the contrary the treatment of virus diseases is of no value after the infection has become established Convalescent serum on the other hand has been employed with success in prophylaxis and in modifying the course of certain diseases including measles mumps and chicken pox The antibiotics have thus far been found to be almost wholly without beneficial effects in the treatment of virus diseases Heilman and Herrell (1944) found penicillin to be effective in the treatment of ornithosis but Kramer et al (1944) suggested that the action of penicillin was not curative even though the mice remained well for appreciable intervals of time since the virus could be recovered from the brain and other tissues of such animals Evidence is accumulating to indicate that aureomycin a new antibiotic prepared from *Streptomyces aureofaciens* and Chloromycetin may prove of value in the treatment of diseases caused by members of the psittacosis lymphogranuloma group

Knowledge about this mode of transmission made it possible to combat yellow fever by controlling the vector. The first anti *aegypti* campaigns in Havana, Panama, and Rio de Janeiro gave spectacular results

The second fundamental discovery is the susceptibility of monkeys to yellow fever In 1927 Stokes, Bauer, and Hudson, working in Nigeria, West Africa, managed to produce yellow fever in the Asiatic *rhesus* monkey *(Macaca mulatta)*. Thus, it was possible to study the disease in a laboratory animal, and many uncertainties concerning its etiology, pathology, and immunology were elucidated, increasing enormously our knowledge about this illness

The third important discovery was made by Theiler in 1930 This worker demonstrated that yellow fever virus produced in white mice, when inoculated directly into the central nervous system, a fatal encephalitis with multiplication of the virus and permitting serial passage In this manner a laboratory animal became available which had many advantages over the *rhesus* monkey, because mice are more easily obtained and they are much cheaper Thus, studies of the virus progressed very rapidly, resulting, in a short while, in the development of an efficient vaccine and of a neutralization or protection test

The fourth discovery of great importance is the finding that yellow fever may exist in nature in the absence of *A aegypti*

In 1932, Soper studied an epidemic of yellow fever in the State of Espirito Santo, Brazil, in which the urban mosquito *A aegypti* could not be incriminated as the vector (Soper et al, 1933) Later, similar epidemics of great extension occurred in other regions of Brazil as well as in other South American countries this new epidemiologic modality of the disease has been called "jungle yellow fever"

GEOGRAPHIC DISTRIBUTION

Surveys dealing with the distribution of immunity have shown that yellow fever is much more widely distributed in Africa than was originally thought, and these studies have made it possible to determine the approximate boundaries of the immunity zone on that continent (Sawyer and Whitman, 1936) Studies made by Mahaffy, Smithburn, and Hughes (1946) indicate that the disease has recently occurred in the Belgian Congo, Uganda, Anglo Egyptian Sudan, Eritrea, Somaliland, Kenya Colony, and Northern Rhodesia To the east, positive tests have been obtained up to the coast of the Red Sea in Eritrea, and to the south all the way to Balovale in Northern Rhodesia In Tanganyika Territory and Zanzibar no indications of recent infection have been found Abyssinia has not been adequately studied

In Central America and Mexico the studies by Kumm and Crawford (1943), in which about 4,000 blood samples were collected in eighty five localities and examined for the presence of neutralizing antibodies, show that only in the region east of Panama have cases occurred in recent years Most of the South American countries have been visited by yellow fever since 1925, with the exception of Chile and Uruguay, in accordance with immunologic surveys (Soper, 1937)

It is the opinion of certain epidemiologists that the Amazon valley constitutes a permanent focus of yellow fever, which is principally maintained in jungle animals From this enormous endemic region epidemics originate from time to time and invade the more densely populated areas

The series of epidemics which broke out in the central and southern states of Brazil, beginning in 1934, are a classical example of this invasion (Soper, 1938) Starting in the state of Goiaz, the disease spread over the entire southern part of this state and a portion of the state of Minas (
during the succeeding
1935 to 1936, this time
ing during the winter and reappearing during the hot season, in contiguous regions, until the epidemic burned itself out after having passed through the southern part of the state of Minas Gerais as well as the states of Rio de Janeiro and Espirito Santo, and to the south through Paraná and Santa Catarina

CHAPTER 18

YELLOW FEVER

HENRIQUE DE AZEVEDO PENNA

Yellow fever is an acute infectious disease caused by a specific virus and transmitted by certain species of mosquitoes. It attacks man and certain sylvatic animals, especially monkeys, and occurs generally in the form of epidemics and epizootics. In nonfatal cases a permanent immunity is established.

HISTORY

Yellow fever probably has existed in America and Africa since time immemorial. However, the first descriptions which permit identification of this illness with some degree of certainty date from the middle of the seventeenth century in America,* and only in 1778 was it recognized in Africa† (Carter, 1931).

At the beginning a great variety of names was given to this disease. Among these may be mentioned *vomito prieto*, used by the early Spanish observers, which called attention to a very characteristic symptom. The name "yellow fever" was introduced later to describe this malady. It originates from the jaundice which so frequently is a part of the clinical picture (Griffith Hughes, 1750, cited by Carter).

During the eighteenth and nineteenth centuries this disease, which is essentially a tropical one, was carried to other regions by ships transporting not only people suffering from yellow fever but also the mosquito vector, which found suitable conditions for its propagation in the water containers on board.

Certain large cities became endemic foci and served as sources for disseminating the illness to regions far from the tropical zone. In these new regions it occurred in the form of epidemics which generally burned themselves out, as the vector could not survive the hardships of the cold season.

Various cities of the United States were thus stricken.

The epidemic in Cadiz, Spain, in 1730 marks the first introduction of this disease into Europe.

Whether yellow fever originated in Africa or America is a question which has been much discussed and probably a satisfactory answer will never be found. It is certain, however, that the virus must have been brought many times from Africa to America and carried there, especially on the slave ships.

The beginning of the twentieth century saw the start of an era which can appropriately be called the scientific era of yellow fever, during which various discoveries were made which constitute real milestones in the history of this disease.

The first of these discoveries is the transmission of the disease by the mosquito *Aedes (Stegomyia) aegypti*.‡ The study which proved this fact beyond a doubt was initiated in 1900 in Havana by the American Army Commission under the direction of Walter Reed (Senate Document No. 8[illegible], 1911). The theory that yellow fever was transmitted by *aegypti* had been formulated in 1881 by C. Finlay, chiefly on the basis of epidemiologic considerations.

* The epidemic of Yucatan in 1648. Lopez de Cogolludo's report, 1688.

† Schotte's report published in [illegible]8[illegible], describing the epidemic in San Luis in Senegal, 1778.

‡ *Aedes (Stegomyia) aegypti* Linnaeus, 1762, is the correct name of the species. It should be noted, however, that this mosquito has been mentioned in the medical literature under many names, among others *Stegomyia fasciata* and *Aedes argenteus*.

icterohaemorrhagiae the cause of Weil's disease (Noguchi 1919, 1925) This point of view was widely accepted until 1927, when the possibility of studying the disease experimentally in monkeys furnished means of correcting this error

LABORATORY DIAGNOSIS

Isolation of Virus

To isolate virus blood or serum which has been taken from the patient during the first three days of fever is injected into a series of 6 or 12 white mice Each mouse is inoculated intracerebrally with 0 03 c c of the material which should preferably be injected immediately after it has been collected

If virus is present, the animals will become sick and die usually after a week It is advisable to make passages with the material from one of the sick mice to another group before trying to make an immunologic identification of the agent

Neutralization Test

The neutralization test serves a double purpose (1) to identify yellow fever virus and (2) to determine the presence of specific antibodies in a given serum sample

Identification of the Virus—After a few serial passages in the brains of white mice the virus adapts itself to and kills mice more regularly but after a longer interval than in the first passage A suspension in physiologic saline is prepared from the brains of mice which have become sick as a result of infection with this modified virus To various dilutions of this suspension a constant quantity of a known immune serum is added There should also be a control with a serum known to be nonimmune Each mixture is injected intracerebrally into a group of 6 or 12 mice The virus will be that of yellow fever if the immune serum protects the animals in one or more dilutions provided that mice which received normal serum and the virus succumb

Determination of the Presence of Specific Antibodies in a Serum.—The unknown serum is added to a filtered suspension of triturated brains from mice which have become sick after the inoculation of neurotropic yellow fever virus Generally desiccated material is used The dilution of the suspension is calculated in such a manner that a virus concentration is obtained which with certainty, can be neutralized by an equal volume of a standard immune serum, and which is sufficient to kill all the animals when mixed with the same volume of normal serum

Three hundredths of a cubic centimeter of the mixtures of unknown sera and the virus are injected cerebrally into each of 6 mice After a few days encephalitis can be noted in the animals if the sera do not contain neutralizing antibodies whereas all mice which received sera containing such antibodies will remain well These tests are usually made with many sera in a single run, always including controls with sera which are specifically known to be positive and negative (Theiler, 1933, Sawyer and Lloyd 1931)

This test serves to make an accurate diagnosis when made with two serum samples—one collected during the first days of the illness and the other during the convalescent period

In the case of yellow fever the first sample should be negative and the second positive

By means of protection or neutralization tests retrospective diagnoses of yellow fever can also be made in any given population and from the age of the youngest individual found immune the date of the last

By this means studies have been made to yellow fever which has been found to be anticipated (Sawyer, 1934)

For a decade, viscerotomy posts in the states of Amazonas and Para have consistently produced a few positive cases each year, indicating that the disease remains endemic in the forests of the Amazon river valley

No yellow fever exists in Asia The reason why the disease has not invaded certain points on the Asiatic continent, where the vector *A aegypti* is found in abundance, is not known

ETIOLOGIC AGENT

In 1901, the American Commission in Havana showed that the causative agent of yellow fever is filtrable through Berkefeld candles However, only after the discovery in 1927 of an animal in which the disease could be experimentally produced was it possible to demonstrate that this etiologic agent has the characteristics of a so called filtrable virus

In man the virus is found in the blood up to the third or fourth day of the disease Later it disappears from the circulation giving place to antibodies capable of neutralizing it During the period in which the virus is found in the blood of man and other susceptible vertebrates it may infect certain species of mosquitoes which feed thereon

The virus does not multiply in culture media which do not contain living cells

Yellow fever virus measures approximately 20 millimicrons (Findlay and Broom 1933 Pickels and Bauer 1940) and is therefore classified among the smallest of viruses It keeps poorly at room temperature At very low temperatures such as those obtained with dry ice (−78° C) it will remain active for long periods of time The best process of preservation however consists in desiccating the virus rapidly in a vacuum in the frozen state (Sawyer Lloyd and Kitchen 1929) When dry and kept in sealed glass containers it will *remain active for several months in a refrigerator (8° C) and for an almost indefinite period* of time at temperatures below 0° C

When inoculated into rhesus monkeys it will produce a disease similar to that found in man Other species of monkeys can also be infected but they rarely die the rhesus therefore has been particularly valuable for experimental work

When introduced into the central nervous system of white mice yellow fever virus produces a fatal encephalitis It can be kept alive through serial passages in this animal when inoculated by the intracerebral route After a certain number of passages alterations occur and as a result the virus will no longer produce yellow fever in man or monkeys This modified virus is called *neurotropic* and has been employed in the vaccination of human beings (Sawyer Kitchen and Lloyd 1932 Laigret 1934)

When inoculated into developing chick embryos a few days old the virus multiplies and can be maintained serially This observation has a practical application in the preparation of vaccine (Elmendorf and Smith 1937)

The virus also multiplies though such high titers are not obtained in embryonic tissues from mice or chickens maintained alive in vitro (Lloyd Theiler and Ricci 1936) Through serial cultures in embryonic tissue it has been possible to obtain a modification of the virus which has been extensively employed in the immunization of human beings This strain is known in the literature by its laboratory designation 17D (Theiler and Smith 1937a

The modification consists of an attenuation of the virulence resulting not only in *the disappearance of the property of producing yellow fever, but also in a greatly reduced* neurotropism or the capacity to produce encephalitis

Noguchi stated in 1919 that the etiologic agent of yellow fever was a filtrable Leptospira to which he gave the name *Leptospira icteroides* morphologically similar to *Leptospira*

placed in glass containers with a 10 per cent solution of *formalin in physiologic* saline, and afterward they are sent to the laboratory (Rickard, 1937)

Through the viscerotomy service, yellow fever has been discovered in various regions where its existence was not previously suspected (Soper, Rickard and Crawford, 1934) In Brazil alone there are 1,303 viscerotomy posts in operation, and during the past sixteen *years 365,584 liver specimens have been* collected and examined

Complement Fixation

Many attempts have been made to use the complement fixation reaction in yellow fever studies *Aragão, Moses, Frobisher, G E Davis, Lennette, and* Perlowagora are some of the investigators who have studied this problem

More recently Perlowagora and Hughes (1946), working with a purified antigen have obtained results useful for epidemiologic investigations

Since complement fixing antibodies in the blood of man and susceptible *animals disappear after a relatively short period of time, while neutralizing* antibodies persist, it is possible to draw conclusions regarding the probable date of infection by carrying out both tests simultaneously

EPIDEMIOLOGIC VARIETIES AND VECTORS

Immunologically, pathologically and clinically yellow *fever* is one and the same disease in America and in Africa Epidemiologically, however, two forms are recognized an *urban form* which is transmitted from man to man through the mosquito *A aegypti* and another variety known as *jungle yellow fever,* which is transmitted by vectors other than *A aegypti* (Soper 1936)

The presence of the virus, *of the aegypti* mosquito, and of a susceptible human population are the necessary factors for the maintenance of urban yellow fever

The virus is present in the blood stream of the patient up to the third day of the fever *A aegypti* which feed upon such blood become capable of transmitting the disease after a few days' period, which is called the *extrinsic incubation period* (Carter, 1900), and remain infective for the rest of their lives

The extrinsic incubation period, which in nature is about 12 days, can be interpreted as the time necessary for the virus to multiply in the mosquito so *that it reaches* the salivary glands

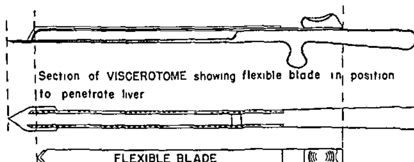
The life span of *A aegypti* is approximately three months.

Only the females feed on blood and are infected in nature

All experiments aimed at demonstrating hereditary transmission of the infection in mosquitoes have failed

A aegypti is essentially a domestic insect, which for oviposition *prefers small water* containers found inside of or in close proximity to human habitations

The immunity conferred by yellow fever is absolute and permanent, and therefore the urban form of the disease would disappear from a locality were it not *for the fact that* the susceptible population is renewed through the introduction of nonimmune individuals coming from other places, or infants born in that locality Such spontaneous elimination of the disease has in fact occurred, because in order *that this might happen it is not necessary* that



it is merely sufficient that the reduction of non

combating the vector has reduced the urban

form to a condition of secondary importance

Viscerotomy

In fatal cases, histopathologic examination of the liver, when made by an expert, usually furnishes information of great diagnostic value Based on this fact, services for the collection of liver specimens on an extensive scale, from fatal cases of febrile illnesses of short duration, have been organized in various countries

Top view of viscerotome with flexible blade withdrawn

Drawing Nº 2

Cutting end of viscerotome with flexible blade in position to penetrate the abdominal wall of the body

Drawing Nº 3

The same end of the viscerotome with the flexible blade in position to enter the liver

Fig 133

These liver specimens are removed from the cadaver by an instrument called viscerotome (Rickard, 1931), which has been distributed to special agents in the indicated zones "Viscerotomy" is easily done, and the collection of such material can be carried out by laymen The liver specimens are

and even vomiting Albuminuria is almost always present These sympt disappear within a few days and the patient recovers completely

The clinical diagnosis of this benign form of yellow fever can rarely made in isolated cases, that is to say, outside of epidemics It is, however, most common form of this disease and is responsible for the majority immune individuals found in nature

In more severe cases the general state of health declines rapidly symptoms of intoxication appear The patient is very restless Vomi occurs frequently and the vomitus may be of a dark color due to hemorrha in the gastric mucosa The stools may also be dark Jaundice appears patient shows great prostration Oliguria, followed by anuria and coma is p of the terminal picture when death occurs Fatalities most frequently oc between the fifth and the eighth day of illness

There exist however possibilities of survival even in very severe c showing all the symptoms of the so called classical cases

Some of the *symptoms* or phenomena deserve special mention

Frequently the *fever*, which is high at the onset (39° 40° C) does fall much during the course of the disease, whereas the rapid pulse no initially slows down causing a discrepancy between the pulse and the te perature, which is known in the literature as *Faget's sign* (Faget 1875)

Albuminuria is one of the most common symptoms and is of considera value for clinical diagnosis In benign cases it may be very slight but it rarely absent In severe cases it is very intense and may be measured in gra per liter Almost always albuminuria is present from the onset

Pronounced *oliguria* is a symptom of the advanced phase of the disease a is an important factor in giving a bad prognosis

Hemorrhages during the initial phase are almost invariably related to t nasal mucosa and the gums If this blood enters the stomach it may la be vomited in the form of black vomit However, the real black vomit is deriv from hemorrhages in the gastric mucosa and is rarely encountered in the init stages In some cases where violent hemorrhages are involved unaltered blo is vomited because sufficient time has not elapsed to permit the action of t gastric juices At times hemorrhages may be generalized hematemesis meler epistaxis and cutaneous hemorrhages occurring simultaneously

The *jaundice* in yellow fever is in many cases not as striking as the nar of the disease might indicate and it appears relatively late Frequently it only a yellowish tinge most noticeable in the sclerae becoming more pronounce toward the end of the disease There are, however, cases in which the jaundi is intense After death it is generally more easily recognized

The clinical diagnosis during epidemics can usually be made with co siderable certainty in the more severe cases and with reasonable accurac in benign ones The diagnosis of isolated cases however, should always b based on laboratory procedures among which the most exact is *the isolatio* and identification of the virus If this is not possible, then one may compar

The *jungle form* was recognized for the first time in 1932 during an epidemic in Vale do Canaa, Espirito Santo, Brazil (Soper et al 1933). It was not possible at that time to determine the vector.

Following this outbreak various epidemics were observed in Brazil as well as in other South American countries, which furnished opportunities for the study of the epidemiologic characteristics of this form of the disease.

Only persons who live near the woods or who enter the forest by chance or to work are attacked.

It seems to be well established that the virus can exist and propagate in the forest without the presence of human beings and that the latter frequently play the role of accidental victims only.

Neutralizing antibodies against the virus have been found in the blood of forest animals, especially monkeys, which indicates that some of them are infected in nature. On one occasion yellow fever virus was isolated from the blood of marmosets captured in the woods near Ilhéus in the state of Bahia, Brazil, without the appearance of any known human cases in that neighborhood (Laemmert, Ferreira and Taylor 1946).

Yellow fever virus was isolated from *Haemagogus capricornii* Lutz and *Aedes leucocelaenus* Dyar and Shannon (Shannon et al 1938).

Bugher et al (1944) showed that Haemagogus mosquitoes were more abundant in the tree tops, which seemed to be their natural habitat. Mosquito captures which until then had been made at ground level did not furnish a true indication of the abundance of these insects in the forest. This observation explained the apparent scarcity of Haemagogus mosquitoes in woods where the disease was known to exist, the survival of the virus from one rainy season to another, as well as the occurrence of a great number of cases of yellow fever among wood cutters.

In Africa it has been difficult to prove the existence of jungle yellow fever, that is to say, the transmission of the disease by mosquitoes other than *A. aegypti*, principally due to the wide dissemination of that species. In various regions of Africa this insect shows an unusual type of behavior, being found in uninhabited forests where it breeds in tree holes.

During an epidemic in 1941 in the proximity of the Semliki forest, Uganda, yellow fever virus was isolated from two lots of *A. (Stegomyia) simpsoni*. The immunity rate in monkeys captured in that area was 61 per cent.

In 1942 the virus was again isolated from *A. simpsoni* in the complete absence of any known human cases, which indicated the probable existence of an extrahuman cycle.

As *A. simpsoni* normally inhabits the forest edges, further searches for other sylvatic vectors were made and in April 1944 virus was isolated from a group of Aedes captured in the interior of the Semliki forest, which included neither *A. aegypti* nor *A. simpsoni*. This observation demonstrated the existence of yellow fever in Africa in the absence of human beings, as the Semliki forest is not inhabited by man (Smithburn and Haddow 1946). *A. africanus* appears to be the forest species most likely to be implicated.

CLINICAL FORMS, SYMPTOMS, DIAGNOSIS AND TREATMENT

There is a great variation in the severity of yellow fever. Generally two distinct phases mark the course of the disease: the first, a period of general reaction or infection, and the second, a period of intoxication in which the symptoms are principally caused by liver damage. In many cases the symptoms are so mild and noncharacteristic that yellow fever is not diagnosed at all but receives a vague denomination such as grippe.

On opening the abdominal cavity, a brownish yellow color of the liv is noted which becomes even more evident after the organ has been remove and exsanguinated This color is said to resemble chamois yellow or the colo of boxwood

The lobular pattern is distinguishable on cut section which shows the sam coloration as the surface of the liver There is no alteration in the size of th organ

The dark contents of the stomach can generally be seen through its wal After opening the contents are found to consist of dark brown material whic has often been compared to coffee grounds On other occasions the stomac contains a yellowish fluid in which dark particles of partially digested bloo are floating In the gastric mucosa there will be found aside from capillar congestion varying numbers of small black spots corresponding to the place where hemorrhages have occurred

Macroscopic examination of the other organs will reveal nothing unusual except the general yellowish tinge which is most marked in such places as the subcutaneous tissues or the inner surface of the large blood vessels and in dications of hemorrhages which may be found in almost any organ

The macroscopic lesions encountered at autopsy are not of a nature which permit an undoubted diagnosis of yellow fever and indeed several other dis eases may present a similar appearance especially certain types of poison ing

Microscopic examination reveals lesions of the kidneys heart spleen and other organs

It is in the liver however that pathologic changes of the greatest diagnostic value are to be found Examining the tissue with the low power of the micro scope a certain disorganization of the parenchyma can be distinguished which is most apparent in the midzone of the lobule There is a jumbling of the liver cords with distortion of the sinusoids The presence of fatty droplets in the cytoplasm of the hepatic cells is a constant finding

The principal lesion however, is the necrosis of the parenchymatous cells In sections stained with hematoxylin and eosin the necrotic cells stand out as rounded bodies highly acidophilic and surrounded by a narrow clear zone as if shrunk Nuclei also acidophilic may be distinguished from the cytoplasm only with difficulty In such cells a nucleus is sometimes found flattened against its surface and believed to belong to a phagocytic cell Councilman (1890) was the first to describe the appearance of the necrotic liver cell in yellow fever and for that reason cells or parts of cells with this type of de generation are known as Councilman bodies" The distribution of these bodies in the microscopic section is very characteristic They are scattered over almost the entire lobule in an irregular manner usually isolated and are more abundant in the midzone of the lobule Rocha Lima (1912) called attention to this midlobular predominance and to the spotty distribution of the necrotic cells There is no tendency to focal necrosis and all lobules are

two blood samples for the presence of specific antibodies The first sample should be taken during the first three days of illness and the second during the period of convalescence

In fatal cases histopathologic examination of the liver usually permits the making of a definite diagnosis

Among those diseases which occur in epidemic form and which may show a resemblance to yellow fever one might mention Weil's disease malaria relapsing fever and dengue In the first three the identification of the etiologic agent establishes the diagnosis The absence of severe or fatal cases in dengue is an important characteristic in differentiating the two diseases

No specific treatment is known against yellow fever

The application of immune serum is of value only as a prophylactic measure

When the serum is introduced before or simultaneously with the virus in experimental inoculation it prevents the disease The intracellular habitat of the virus does not permit antibodies introduced after the virus to exert any effect at all

Liver necrosis which is the principal lesion responsible for the symptoms of the disease develops rapidly and since it is an irreversible process it is not susceptible to any treatment whatsoever

Experiments directed at neutralizing the toxic effect caused by the destruction of the liver the administration of calcium salts which has given satisfactory results in certain other intoxications also caused by liver necrosis have been in vain *

It is however advisable to follow certain general rules in the symptomatic treatment of patients (Soper 1942)

Transportation of the patient from one locality to another should be avoided

A laxative may be given on the first day The food intake should be limited to fruit juices

Depressant antipyretics should not be used

Convalescence is at times prolonged The patient should therefore not reassume his activities too soon particularly if they involve heavy physical exertion

MORBID ANATOMY

The general appearance of the cadaver in yellow fever is not characteristic

Jaundice when present is more easily recognized than during life In certain regions ecchymotic patches on the icteric skin produce a purplish appearance

Flecks of dried blood around the mouth and nostrils indicate the occurrence of hemorrhages

*One of the editors (O F) recently suggested the use of vitamin B_1 and methione

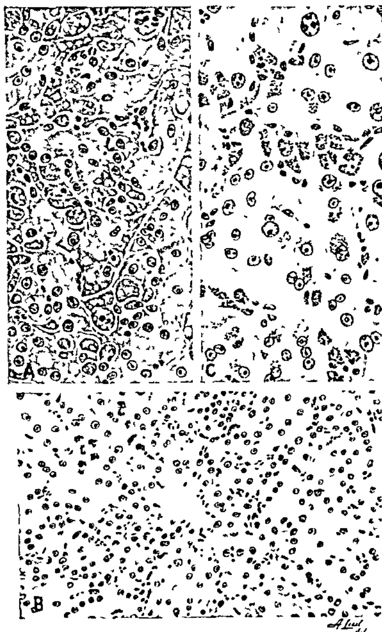


PLATE II — *A* Classical picture of yellow fever in section of human liver stained with hematoxylin and eosin. Councilman bodies are distributed throughout.

B and *C* Sections of human liver in which the classical picture is not found but in which bright ochre-colored granular bodies are scattered throughout the lobule with the greatest concentration in the midzone. These granular bodies have been used as a basis for the diagnosis of yellow fever in cases in which eosinophilic Councilman bodies could not be found.

(From Villela, F.: Histology of Human Yellow Fever when Death Is Delayed. Arch. Path. **31**: 665-669, 1941. Reproduced by permission Archives of Pathology, the American Medical Association and the Rockefeller Foundation.)

Coun ilman l od es sta ne l p nk A nu l u bel e ed to elo to a pl ocyt c cell can be seen fl ttened aga nst one of tl e e l od e

curred between the eighth and seventeenth day The diagnosis was based on the presence of rounded granular bodies of a vivid ochre yellow color predominantly distributed in the midzone of the lobule Villela believed that they represent Councilman bodies already in a stage of disintegration

When viscerotomy service was begun in Brazil it was believed that the microscopic findings in the liver were sufficiently characteristic to permit the establishment of a diagnosis per se As wider experience was gained from suspect cases and through field investigations it was found that other diseases might show similar findings or even reproduce the histologic picture of the yellow fever liver

Only an examiner with great practice is therefore in a position to distinguish the lesions found in yellow fever from those encountered in certain rare cases of acute yellow atrophy, peritonitis meningitis poisoning with arsenic antimony or carbon tetrachloride the latter being widely used as a vermifuge

Belt (1939) described liver lesions found in cases of severe burns which had been treated with tannic acid and these lesions were indistinguishable from those produced by yellow fever

However none of these observations are of such a nature as to interfere seriously with the practical value of viscerotomy

In the majority of cases an expert can make the distinction and field investigations usually clear up the remainder of cases in which confusion still persists

PROPHYLAXIS

Anti Aegypti Measures

The maintenance of urban yellow fever depends on the cycle man-*aegypti* man

The most practical method of interrupting this cycle and thus controlling the disease consists in combating the mosquito

In order for yellow fever to disappear from a locality it is not necessary to eliminate the vector completely It is sufficient to reduce it below a critical number (Carter 1931)

The *aegypti index* is the per cent of houses found harboring larval foci

In the past it was believed that only the big urban centers could maintain the disease endemically due to the constant introduction of nonimmune individuals and that if these seedbeds were destroyed the disease would disappear from all nearby places through the process of spontaneous elimination

Although this program of mosquito control in key centers proved successful in certain places it failed in others

In the northeastern part of Brazil for instance during the campaign which began in 1923 with the cooperation of the Rockefeller Foundation yellow fever disappeared from the principal cities on the coast but continued to occur in villages and among the smaller towns of the interior

The demonstration of the existence of the jungle form of the disease and of the possibility of the importation of the virus from the forests to the cities

uniformly affected. Even in cases where the major part of the liver cells are necrotic some cells can still be seen around the central vein which have not been affected.

The degree of necrosis varies from individual to individual, ranging from 5 to 100 per cent, with an average of 80 per cent in a series of cases studied by Klotz and Belt (1930a).

The cells which have not undergone necrosis present different stages of degeneration from cloudy swelling to an advanced stage of necrobiosis. Such necrobiotic cells are characterized chiefly by a granular and vacuolated appearance of the cytoplasm and are generally increased in size. The nuclei show swelling and margination of the chromatin and one or more nucleoli are easily visible. Sometimes acidophilic substances are encountered in the nuclei forming aggregations which Torres (1928, 1931) identified as nuclear

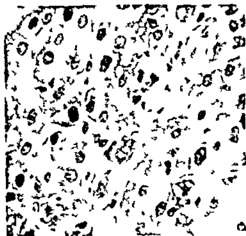

Fig 134—Biopsy of the liver in yellow fever showing fatty degeneration and acidophilic cells (Courtesy of Oscar Felsenfeld)

inclusions. In human viscerotomy material collected in Brazil nuclear inclusion bodies are rarely found and can be considered as exceptional so that they are of diagnostic value only when present. In the experimental disease in rhesus monkeys, on the other hand, intranuclear inclusions almost invariably form part of the histologic picture and are thus of value in making the diagnosis. They may also be found in the nuclei of certain cells of the nervous system in mice and monkeys which have died from yellow fever virus encephalitis.

The alterations found in the liver are of a degenerative character rather than inflammatory, although some leucocytes may be encountered.

In cases that survive, regeneration of the liver tissues is rapid and complete, with no residual fibrosis (Klotz and Belt 1930b).

Villela (1941) described a histopathologic picture in the liver which permits the diagnosis when death is delayed and presumably is caused by some intercurrent disease. Twenty three cases were studied where death had oc

tinued to be injected simultaneously (Lloyd Theiler, and Ricci, 1936) In order to reduce the volume of the serum injected, hyperimmune monkey serum was later employed This was obtained by injecting massive doses of the virus into an already immune rhesus monkey and collecting the serum nine days later when the maximum concentration of antibodies occurs (Theiler and Smith 1936)

Beginning with 1937 however a strain of virus so attenuated that it no longer requires the complementary use of immune serum has been employed on a large scale for the immunization of human beings

This modification of the virus was obtained by serial cultures in chick embryo tissues from which the major portion of the nervous tissue had been removed This strain is known as 17D (Theiler and Smith 1937a 1937b)

Several million people have already been vaccinated with the 17D strain of yellow fever virus principally in Brazil and among the Armed Forces of the United States

At the time when the vaccine is to be used it is diluted to contain not less than 1 000 MLD for mice to each 0 5 c c the volume injected into each person preferably subcutaneously *

Certain accidents have occurred during mass vaccination campaigns of which the most serious was the appearance of jaundice among persons vaccinated This illness is known as homologous serum jaundice

Postvaccination cases of jaundice of late appearance had already been reported by Findlay and MacCallum (1937) in England and by Soper and Smith (1938) in Brazil after vaccination with modified virus and supplementary immune serum

When the 17D strain of virus was first used without immune serum more than a million persons were vaccinated without cases of jaundice having been known to occur

At the beginning of 1940 an outbreak of postvaccination jaundice was observed in the state of Espirito Santo Brazil where more than a thousand cases were investigated which were principally related to the use of two vaccine lots believed to have been contaminated by an icterogenic agent derived from what was supposed to be normal human serum that had been used in the preparation of those lots of vaccine Some fatal cases were recorded The principal lesions were found in the liver and corresponded essentially to those described in cases of acute or subacute yellow atrophy of the liver (Fox et al 1942)

In 1942 another outbreak of postvaccination jaundice was noted among the Armed Forces of the United States (Sawyer et al 1944)

These accidents caused a temporary interruption of the vaccination program and investigators directed their efforts to finding means of perfecting the methods of preparing vaccine so as to eliminate the possibility of contamination by such icterogenic agents

*Editor's note (O F) Fox et al (Am J Hyg 38 113 1943) recommended only 500 MLD (LD_{50}) for mice for human vaccination

where it may be spread by *A aegypti* finally brought an end to this key center theory and indicated the necessity of a program of eradication wherever *A aegypti* were found (Soper and Wilson 1942)

The anti *aegypti* measures adopted by the National Yellow Fever Service of Brazil may serve as a model for similar campaigns that may be organized in other countries because the efficiency of the methods finally adopted has been tested through many years of practical application

Brazil which extends over a territory that measures 8 542 000 square kilometers has been divided for administrative purposes into six "circumscriptions" and these in turn in sixteen sectors each directed by a specialist

Some of the procedures used in the beginning such as quarantine isolation of the patient and destruction of adult mosquitoes by fumigation were abandoned in favor of antilarval measures directed against the foci of *A aegypti*

The search for and destruction of these foci are handled by a large group of sanitary inspectors who examine buildings and deal with potential mosquito breeding places by oiling

Other specialized groups of inspectors are employed in the capture of adult mosquitoes in order to give a better orientation to those who are searching for hidden breeding places that may have escaped attention on previous inspections

Successive areas are worked in territorial sequence and those already clean are carefully watched

The final objective is the complete eradication of *A aegypti* from vast areas rather than merely reducing the numbers below the critical level (Soper Wilson Lima and Antunes 1943)

Vaccination

The first attempts at vaccination were made with virus which had been inactivated by chemical substances Results were unsatisfactory

In 1931 in an attempt to put an end to the long series of laboratory infections that were occurring in New York and Africa a certain number of individuals were experimentally vaccinated with active virus The strain used was the one adapted to the nervous system of mice or the so called neurotropic virus This virus when injected subcutaneously into rhesus monkeys confers immunity without producing yellow fever On the other hand when it is injected intracerebrally it produces fatal encephalitis However even when injected subcutaneously it did produce encephalitis in certain exceptional cases For that reason it was considered dangerous to use this strain for vaccination of human beings without simultaneously injecting an adequate amount of immune serum The immunity conferred by the application of this method was satisfactory and no further accidental laboratory infections were recorded (Sawyer Kitchen and Lloyd 1932)

In 1935 the neurotropic virus was substituted for an attenuated virus by cultures in embryonic mouse tissue (strain 17E), but the immune serum con

Senate Document No 822 1911 Yellow Fever A Compilation of Various Publications Results of the Work of Maj Walter Reed, Medical Corps, United States Army, and Yellow Fever Commission, Washington, Government Printing Office

Yellow fever virus does not pass bacteriologic filters well unless its vehicle contains a high percentage of proteins Human serum was added to the vaccine in order to facilitate this filtration process primarily because it was believed to be harmless when inoculated into man The icterogenic agent *which is filtrable and resists heating at 56° C for half an hour was intro*duced inadvertently into the vaccine with this serum component

In order to prevent this hazard filtration of the vaccine has been discontinued and bacteriologic sterility now depends exclusively on rigorous aseptic precautions

No more cases of jaundice have occurred since the adoption of this modification in the technic employed in the preparation of vaccine

Encephalitis vaccination methods utilizing the Dakar strain from mouse brain suspended in arabic gum have been adopted by the Pasteur Institute in French West Africa and have been employed on a large scale in the French colonies in that area Laigret (1934) used three subcutaneous injections in progressively decreasing dilutions spaced over a few days This method although it confers a good immunity caused the occasional appearance of unpleasant reactions which at times involved the nervous system (Sorel 1936)

Since 1939 the French method has consisted of cutaneous scarifications sometimes together with smallpox vaccine

The scratch method simplifies the technic of application 7 890 417 vaccinations having been given in French West Africa from 1939 to 1943 without any serious reactions having been recorded (Rapport sur le fonctionnement technique de l'Institut Pasteur de l Afrique Occidental Française en 1943)

CHAPTER 19

DENGUE AND DENGUE-LIKE FEVERS

Gustavo Pittaluga

DENGUE

Dengue is a benign disease that may assume such widespread epidemic proportions as to become a serious community problem

HISTORY AND GEOGRAPHIC DISTRIBUTION

The term "dengue" was first used in Mexico during the epidemic of 1824 to 1828 This epidemic covered the Atlantic side of the intertropical zone of North America, from South Carolina (U S A) to the Antilles and Venezuela, and particularly the Mexican coast The name is derived from the Spanish word *derrengado* (bent, crooked) or *abatido* (dejected), or from the Spanish American *denguero* (prudish, affected) or *amanerado* (full of mannerisms), and refers to the state of asthenia so characteristically observed in these patients In 1869, the Royal College of Physicians of London adopted this name in its nomenclature, giving the term "dengue" preference over other names for the disease in Europe and America—"*colorado*" (smutty or ruddy), "pantomime," "influenza," "dandy fever," "break bone fever," etc

This disease was first identified as a specific clinical entity in North and South America and the Antilles by the Spanish and French in the middle of the seventeenth century At first (Boyce, 1910) it was called *chapetonada* (a disease of Europeans due to change of climate) because of the eruption It was considered an "acclimatization fever" Others in Guadalupe (1648) described an epidemic of a disease with similar symptoms, and called it *coup de barre* (Finlay, 1912, Levaditi and Lepine, 1938) Later, especially during the nineteenth century, dengu[illegible] on the southern coast of [illegible] in Greece (1845 1865), [illegible] ports (1889), and again in America, from Louisiana (30,000 cases in 1922) down the coast of Mexico as far south as Venezuela, and down to Rio de Janeiro Last, a serious pandemic occurred in Greece and the eastern Mediterranean area in 1927 1928, with an extensive outbreak in Spain This ended, for a time, the epidemic cycles of dengue, with endemic foci left in many places I personally observed the epidemics in Greece and Spain (1928) and later studied a more limited outbreak in Havana (Cuba) in October November, 1944 (Pittaluga, 1945)

SYMPTOMATOLOGY AND DEVELOPMENT OF THE CLINICAL SYNDROME

The disease usually lasts 5 or 6 days The period of incubation is brief 2 to 7 days (*Zuelzer, 1874, Guiteras and Cartaya*, 1906, Manoussakis, 1928; Simmons, 1931) The prodromal period is mild Healthy individuals experience a *mild headache, general indefinite malaise*, and at times a state of excitation at the beginning of the disease The following day there is rapid *elevation of temperature*, 38 5° *to* 39° C, in some cases as high as 40° C, and

erythema of rubeola It varies in color and intensity, according to the endocrine and neurovegetative condition of the patients The rash lasts approximately 2 or 3 days On the sixth or seventh day there is a light epidermic desquamation scarcely appreciable in most cases In some cases, a singular symptom is observed consisting of acroerythroderma, with slight edema of the palms of the hands paresthesia, cramps and itching In some cases there is pronounced muscular asthenia accompanied by diffuse pain in the muscles drawing sensation and in rare cases signs of slight cardiac dysfunction Acroerythroderma when present, often lasts 3 or 4 days The neuromuscular asthenia lasts a week or longer after all other symptoms have disappeared Generally on the seventh day the symptoms subside No splenomegaly is noted There is however a mild hepatic congestion No catarrhal or mucous inflammation of the respiratory tract is observed, nor pulmonary symptoms except in patients with previous bronchopulmonary affections of other origin which may be exacerbated In rare cases a slight subicteric tinge is observed Pronounced photophobia, persistent insomnia vomiting and small mucous hemorrhages (mouth intestine) may be present in some cases but do not constitute true elements of the syndrome More frequently there is slight albuminuria with barely observable traces of albumin, without renal lesions The pulse rate does not increase with the rise in temperature. There is a bradycardia with rarely more than 90 to 100 beats per minute even during the height of the fever The blood pressure is often low Convalescence may be prolonged for 2 or 3 weeks The mortality of this disease, if uncomplicated is nil With the exception of rare complications that originate in some previous illness all patients recover

HEMATOLOGY AND SEROLOGY

Dengue does not cause anemia The red blood cell count usually remains within normal limits, falling at the most, to 4 500 000 on the fifth or sixth day Loss of red blood cells is therefore, very slight, but there may be mild hematoxic signs such as anisocytosis and poikilocytosis Leucopenia is a constant finding In my experience the count fluctuates between 1 000 and 4 000 leucocytes per cubic millimeter on the fifth day, although in most cases it is not below 3 000 (Stitt, 1907, Joannides 1930, Simmons, St John and Reynolds 1931 Pittaluga 1945) The leucopenia is accompanied by a relative monocytosis which may be as high as 14 per cent according to Joannides and others (1930) There may be toxic changes, both cytoplasmic and nuclear, of the neutrophilic granulocytes often with karyorrhexis (fragmentation of the nuclear mass) and pathologic granules There is a left shift in the differential picture Young forms, metamyelocytes and stabs, increase beginning on the third day The differential count and the white count return to normal soon after the beginning of convalescence No immature or pathologic cells have ever been observed in the blood stream (Simmons et al, 1931, Pittaluga 1945)

Coles (1937) described the presence of small endoglobular corpuscles in blood preparations from dengue patients This finding has not been confirmed by other observers

an intense headache severe enough to confine the patient to bed The he ache seldom has the characteristics of migraine It is a cranial pain, so times so pronounced that it requires not only the usual sedatives to wh it responds very little but also the application of ice bags Soon also anorexia occurs at times with veritable pronounced food repugnance th and constipation are also symptoms

These symptoms are accompanied by spasmodic epigastric sensation w out true pain without rigid or painful abdomen without any diarrhea but polyuria and pollakiuria lasting 2 to 3 days It shows at times from

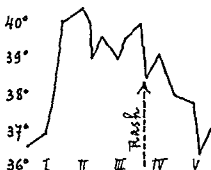

Fig 135 —Temperature curve and appearance of the rash (between the third and fo day) in a case of dengue observed in Greece (Manousakis

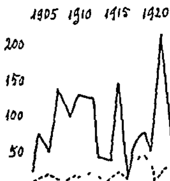

Fig 136 —Graph showing the number of cases of dengue in American soldiers (——— as compared with native patients) in the Philippines from 1905 to 1920 (fig show the percentages for 1 000 individuals in each group) (Silver Hall Hitchens)

first day on a cutaneous hyperemia principally on the face and upper part the body which has an aspect of transitory diffuse hyperemia On the third fourth day there occurs a true exanthem In connection with the sympto described above there appears a crisis the intense headache disappears the fever which tends to be low from the third day becomes normal or some patients there is fleeting hypothermia with more or less marked asthe which can induce a state of syncope The tongue in this period is thic coated There is an eruptive polymorphous rash appearing much like

intensity of propagation, the virulence of the epidemic is shortly exhausted and remains for years in a latent state, with rare sporadic cases among persons not immunized by previous epidemics (Blanc 1938, van Rooyen and Rhodes, 1940)

PATHOGENIC AGENT

It is not necessary to consider here the hypotheses or supposed discoveries of pathogenic agents of dengue which have never been confirmed McMullin (1919) suggested the possibility that dengue is simply an allergic manifestation caused by repeated inoculations of *proteins contained in the fluid* from the salivary glands of mosquitoes We must recall the mistaken theory of the spirochetal nature of the virus of yellow fever which followed *Noguchi's error* (1919) with respect to *Leptospira icteroides* Finally, the possibility of Rickettsiae (Sellards and Siler, 1928) in mosquitoes of the Aëdes genus infected by dengue patients was also disproved and abandoned

The work of Ashburn and Craig in the Philippines (1907) initiated the scientific studies of dengue virus The combined results of the investigations carried out in the last few years are as follows (Blanc, 1938, van Rooyen and Rhodes, 1940) The virus passes through most filters and is found in high concentration in the blood during the period of fever (Blanc and Caminopetros; Manoussakis, 1928, Kligler and Aschner, 1928; Simmons et al, 1931) Cultures in the chick embryo, obtained by Shortt, Rao, and Swaminath (1936), with blood from cases of dengue have caused lesions on the chorio allantoic *membrane*

The virus retains its virulence in the serum of patients at room temperature *for one to two months, according to Blanc and Caminopetros* (1930) The virus resists temperatures as low as -20° C for at least 48 hours (Holt, Fleming, and Kintner, 1931), *and* x-rays and ultraviolet rays Hoffmann, Mertens and Snijder (1932), in Amsterdam, succeeded in transmitting the disease to volunteers by injection of desiccated blood serum shipped from Java and preserved for 285 days Manoussakis demonstrated that the virus is destroyed by heat of 50° C for one half hour

Direct transmission of infected blood to normal individuals causes a typical disease—experimental dengue Mosquitoes become infected when they feed on patients during the first three days of the disease After the fourth *day, the proportion of infected* mosquitoes seems to be less (Kamal) Chandler, Blanc, Caminopetros, and others succeeded in infecting groups of Aëdes mosquitoes with blood of patients on the fifth day of infection The virus can be found in the cerebrospinal fluid *Nasopharyngeal* exudate and urine have always been negative as infecting agents

TRANSMITTING INSECTS

In the Mediterranean basin and in Africa and Central American foci, *A aegypti* is the transmitter In the Philippines, Simmons et al (1930) demonstrated that two species of the same genus, *A albopictus* and *A scutellaris*, can be vectors *A albopictus* is also found in Sumatra, according to Snijder, *Dinger*, and *Schuffner* (1931), who succeeded in [illegible] reproducing typical

Degenerative changes in the leucocytes, particularly the polymorphonuclears, have been ascribed to a circulating leucotoxin in the plasma, perhaps with myelotoxic action (Joannides) This may account for the leucopenia Experimental proof is lacking

Serologic investigations are negative* The serum of patients after an attack of dengue does not seem to contain antibodies capable of neutralizing the virus Blanc and Caminopetros proved during the Greek epidemic that the plasma or the serum of convalescent patients has no protective action in vivo or in vitro (Blanc and Caminopetros in Levaditi 1938)

PATHOLOGIC ANATOMY AND PATHOLOGY

Autopsies have rarely been performed in dengue The pathologic findings reported by some investigators (Corpanaris 1928 Photakis 1929), during the great epidemic, must be accepted with reservations because of the possibility of other existing pathologic processes The only lesions attributable to dengue are hepatic congestion with slight hepatitis without inflammatory foci slight myocarditis congestion or hemorrhagic lesions of the gastrointestinal mucosa Spleen and adrenals are normal There are no lymphatic glandular inflammatory reactions

EPIDEMIOLOGY AND TRANSMISSION

Epidemics of dengue correspond to the geographic distribution of mosquitoes of the genus Aedes (Stegomyia) Graham in Syria (Beyrouth, 1903) first demonstrated the transfer of dengue by mosquitoes without giving the exact species of the vector Later, Cleland, Bradley, and McDonald (1916) in Australia and Siler, Hall, and Hitchens (1926) in the Philippines excluded mosquitoes of the genus Culex, particularly *Culex fatigans* although transmission of the disease in the eastern part of the Mediterranean had been attributed to this species Siler, Hall and Hitchens (1926) proved that transmission is effected by mosquitoes of the genus Aedes particularly by *A aegypti (Stegomyia fasciata)* The great epidemic in Greece in 1928 verified these facts in an incontroversial way Blanc and collaborators (1938) showed that there were two successive epidemics one in the fall of 1927 with approximately 20,000 cases, another from June through October, 1928 The following year 1929, cases appeared only sporadically The number of known cases between July and October of 1928 in the Greek provinces in which Aedes mosquitoes are abundant was close to 800 000 in the districts of Western Macedonia where Aedes is rarely found if found at all, a total of 16[illegible] cases was reported The epidemic of "colorado"† ("ruddy fever") in Andalusia (Spain) in the same year in the Mediterranean littoral and along the river valleys was not seen in areas where the Aedes mosquito is found In the Philippines Simmons et al (1930) confirmed the epidemiologic and experimental data by demonstrating that a local species of the mosquito, *Aedes albopictus* transmits the dengue virus It is apparent, then that the old hypothesis previously presented in Havana (Cuba) at the turn of the century by Agramonte and others can be confirmed that the dengue virus is transmitted to man by the same insect vectors that transmit the virus of yellow fever

Dengue follows the geographic distribution and number of Aedes between 30 degrees north and 30 degrees south latitude In Asia, India, in Africa, the west coast and equatorial Africa, in Europe, the Mediterranean area, in America, the shores of Louisiana through Mexico, the Antilles down to Brazil Through extraordinary rapidity of invasion and the

*A different opinion has lately been expressed by A B Sabin
†Not identical with Colorado tick fever

among the first patients examined at the beginning of an epidemic a differential diagnosis is difficult between grippe (influenza) or some eruptive disease particularly measles or an attenuated form of rickettsiosis (spotted fever) The clinical syndrome of dengue appears quite characteristic to a careful observer it can be readily distinguished from other infectious endemic epidemic processes No matter what part of the body is affected in grippe or influenza including the gastrointestinal form the mucosae particularly of the respiratory tract are always invaded These are not affected in dengue On the other hand the neurotoxic symptoms of grippe are relatively *latent while in dengue these symptoms are prodromal—headache* anorexia asthenia and pyloric splanchnic spasms Last there is no "rash" in influenza as there is in the more or less diffuse form of dengue Caution is advised in dealing with children bearing in mind the possibility of many other conditions of measles particularly The fleeting character of the rash is more pronounced in dengue Signs of congestion of the mucous membranes conjunctiva etc do not occur in dengue as they do in influenza

PROGNOSIS

Prognosis is favorable except in complicated cases Death rate does not exceed 0 03 per cent (statistics of McCallum and Dwyer during the epidemic of Queensland 1927 of Blanc et al in Greece 1928, and of Calvo and others in Spain 1929) During epidemics the hematoxic and neurotoxic effects of dengue increase mortality among patients already affected by chronic disease such as tuberculosis and diseases of the liver and of the heart

Complications not only obscure the prognosis in some cases but may also *affect the differential diagnosis These are (1) gastric hemorrhage* renal complications etc at times mucocutaneous hemorrhages which on certain rare occasions (Georgopoulos 1928) reveal endothelial or vascular origin (2) ocular lesions—iritis keratitis and paralysis of the oculomotor nerve (3) changes in the nervous system particularly neuritis at times transitory psychosis with extreme asthenia, (4) cardiac changes usually functional rarely a true myocarditis

TREATMENT

Treatment is purely symptomatic It necessitates bed rest liquid diet vitamin C or orange or lemon juices Aspirin is given the first few days Antibiotics are of no avail Sulfonamides are dangerous *and should not* be administered because of the leucopenia they are not indicated from an etiologic point of view

PROPHYLAXIS

Individual prophylaxis by vaccination has been tried with doubtful results to date—an active *serum treated with bile* (Blanc and collaborators) * General prophylaxis consists of campaigns to destroy the mosquitoes that transmit the disease

*Editor's note (O F) A very promising vaccine has been described by Sabin, A. B and Schlesinger R. W

The role of *Culex fatigans* in the transmission and epidemiology of dengue has been rejected by Kligler, Aschner, Blanc, and Caminopetros (1929), and others. Transmission of the virus is not a purely mechanical function; it represents a biologic process, the conditions and phases of which are still not known. The mosquitoes are not infectious for 7 to 10 days after biting a dengue patient. The infected insect ceases to be infective when the atmospheric temperature drops to 18° C.

Blanc and Caminopetros (1928) obtained positive results of transmission by infected Aedes after a period of 84 days. These mosquitoes were kept in the laboratory at 22° C. A group of Aedes gave positive results 174 days after they had been experimentally infected. This long survival of the virus may explain, in part, the diffusion and duration of the great epidemic outbreaks, since the same mosquito can infect several persons successively (Blanc 1938).

The identity of the transmitting mosquito, when considered with the corresponding endemic foci, has suggested the probability that dengue virus is merely an attenuated virus of yellow fever. Cuban physicians at the beginning of this century, particularly Agramonte and Guiteras (1906), studied this problem with reference to the differential diagnosis of the two diseases. The more recent experiences with cross immunity, however, show that the dengue virus is capable of producing in monkeys (*Macaca mulatta* or *rhesus*) a certain degree of protective action against inoculations of the yellow fever virus (Dinger and Snijders 1931).

RESULTS OF EXPERIMENTAL INOCULATION

As to experimental inoculation of animals, we must depend exclusively upon results obtained in monkeys. In the lower animals—guinea pigs, rats, rabbits, dogs—the virus can probably be propagated without apparent symptoms, according to Kurauchi et al. (1917), Blanc and Caminopetros (1928).*

IMMUNITY

Immunity developed during dengue infection is possible, but it is variable and usually of short duration. Simmons et al. (1931), Sharp and Hollar (1935), and Blanc and Caminopetros (1930), Manoussakis and others (1931) in Greece agree in assuming that there is acquired immunity for one to four years. In endemic zones at the start of an epidemic, few natives develop the disease, but a large proportion of individuals who live away from the endemic zone, as well as newcomers to the region, become ill. Epidemic outbreaks, even when most intense, as in Greece (1928) or in Spain (1928-1929), terminate abruptly, with only a few sporadic cases remaining. This can be explained only on the basis of an immunity acquired during a mass attack. Finally, experimental observations—inoculation of virus into individuals who have recovered from dengue—point to the existence of very definite immunity.

There is no proof of the existence of any protective action in the sera of convalescents (Holt, Fleming and Kintner 1931, Manoussakis, Blanc and others). Fresh and old sera were both used; some sera were concentrated, some were administered as early as the first day of the disease, some were administered as a preventive measure—yet no protecting antibodies were found.

DIFFERENTIAL DIAGNOSIS

During epidemics, diagnosis of dengue is quite easy, because these cases present a stereotyped syndrome. With sporadic or isolated cases, or even

*Editor's note (O. K.): For mouse adaptation, see Sabin, A. B., and Schlesinger, R. W., 1945, Science, 101, 640.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis is not always easy particularly from the early stages of dengue or from influenza

TREATMENT

Treatment is purely symptomatic Absolute rest is necessary during illness and tonics during convalescence

PROPHYLAXIS

Since no vaccine is available at present prophylaxis must be limited to prevention of bite by the Phlebotomus These insects are not infectious if the atmospheric temperature drops to 54° F (18° C) according to Whittingham and others (1923) Aromatic substances such as oil of citronella keep them away They live in low damp dark places in basements behind furniture etc The upper floors of dwellings are usually free from Phlebotomus Successful campaigns against the larvae of these diptera are more difficult to carry out than against the larvae of the common mosquitoes (Anopheles Culex Aedes)

RIFT VALLEY FEVER

Rift Valley fever is a disease of sheep and newborn lambs and is transmissible to man It was discovered in 1931 in Kenya Colony (East Africa) by Daubney Hudson and Garnham (1931) and later observed by others in the Sudan and in West Africa Cases of experimental accidental infection have been observed in laboratories (Kitchen 1934, Francis and Magill 1935) one with thrombophlebitic complications terminating fatally (Schwentker and Rivers 1934)

CLINICAL SYMPTOMS

Clinical symptoms in man are similar to those of dengue although they are more acute—headache nausea vomiting chills sudden fever (39° C or more) transitory joint and muscle pains hepatic congestion subicteric tint neurotoxic signs vertigo photophobia and at times mental confusion There is also pronounced leucopenia with a tendency toward agranulocytosis Findlay (1932) Francis and Magill (1935), and others observed toxic changes in the cytoplasm and nuclei of granulocytes with persistent leucopenia during the period of convalescence

THE VIRUS

In susceptible animals the virus produces hepatitis with necrotic foci without perihepatitis and without splenomegaly although the spleen in infected sheep and lambs may show hemorrhagic foci Sometimes pericarditis as well as hemorrhagic nephritis is present

PHLEBOTOMUS FEVER (SAND FLY FEVER)

Phlebotomus fever, or sand fly fever, has been known for a long time by a variety of names—"pappataci fever," "three day fever," "dog fever," etc —in Italy and the Balkans It is an acute fever with rapid course, first studied by Doerr et al (1909) The pathogenic agent appears to be a virus transmitted to man by the bite of a small diptera of the genus Phlebotomus especially by the species *Phlebotomus pappatasii*

CLINICAL SYMPTOMS

The clinical syndrome has frequently been confused with dengue It differs in its more rapid course The fever usually lasts for 3 days, increasing to 39° to 40° C (104° F) at first There is intense reddening of the face and congestion of the conjunctiva (swollen and bloodshot eyes "dog eyes" hence the German name 'Hundskrankheit" or the English "dog disease") There is no real 'rash ' but dry skin with papules and isolated vesicles extending in many cases to the tongue palate and mucous membranes of the mouth Hypersensitivity often localized pains in various parts of the body indicates possible involvement of the nervous system in the disease Trabaud (1931) observed these nervous symptoms Jayle Mastier and Rameev (1935) described neuroretinitis in some cases, LeGac and Albrand and others (1937 1940) noted alterations of the cerebrospinal fluid—increase of pressure, albumin, and cell count These observations proved the neurotoxic action of the virus Relative bradycardia even during the short period of fever, and especially persistent leucopenia (van Rooyen and Rhodes 1940) around 3 000 to 3 500 leucocytes per cubic millimeter (on the fourth or fifth day) without anemia are characteristics in common with dengue

EPIDEMIOLOGY AND GEOGRAPHIC DISTRIBUTION

Epidemiology and geographic distribution of the disease are related to the ecology of Phlebotomus, particularly *Phlebotomus pappatasii* Shortt Endemic foci are found in the Balkans [illegible]
[illegible]

Diptera of the genus Phlebotomus are transmitters of pathogenic protozoa of the genus Leishmania These protozoa produce diseases important in tropical pathology, such as kala azar and espundia The possible relationship between sand fly fever and leishmaniasis has not been studied and is therefore unknown They are two entirely different diseases.

The virus of sand fly fever has been studied during the past few years by Kligler and Aschner (1928) by Shortt Poole and Stephens (1935) Shortt Pandit, and Rao (1939), and others It has been cultivated on the chorioallantoic membrane of the chick embryo and in tissue cultures and successfully inoculated into monkeys (Macacus) (Tedeschi and Napolitani, 1911 Shortt Poole and Stephens 1935) It remains virulent upon experimental animal inoculation Lower mammals are refractory to it Acquired immunity is brief, according to Lepine Lambert Shortt, and collaborators (1935) although McCarrison demonstrated that injection of 2 c.c. of infective blood did not produce symptoms of the disease in subjects who had recovered from an attack (Birt, 1915)

Zuelzer, W 1874 Pathol de Ziemssen, Leipzig 2 482

The virus is filtrable as is that of dengue According to observations of Broom and Findlay (1933) it is about 23 to 35 millimicrons Certain species of African monkeys such as the Cebus are particularly susceptible to the virus (Findlay 1932) The virus is decidedly pathogenic for rodents (Rattus, Epymis Cricetus Microtus and others)

Protective antibodies have been found in the blood of experimentally infected animals These antibodies are able to neutralize 1 000 rat units of the virus (Schwentker and Rivers 1934) Findlay and MacCallum (1937) demonstrated a certain degree of antagonism between the virus of Rift Valley fever and the virus of yellow fever Other observers have insisted upon a possible common origin of the two viruses which cause very similar hepatic cellular lesions and which are probably transmitted by the same mosquitoes of the genus Aedes Daubney and Hudson however stated that the virus of Rift Valley fever can survive on the pupa of the tick of *Rhipicephalus appendiculatus* for 7 days without losing its virulence It may also be transmitted by direct contact (van Rooyen and Rhodes 1940)

established by Leichtenstern (1898), who investigated several outbreaks in Cologne Prior to 1929, psittacosis was rare in England (Beddoes, 1914, and Thomson, 1929) and in the United States An outbreak in Wilkes Barre, Pennsylvania, reported by McClintock in 1917, resembled in many ways those occurring in this country during the past seventeen years The infection had doubtless been endemic in bird stores for many years but had escaped detection as a human disease Although the Paris epidemic of 1892 was caused by parrots coming from South America, only one case in 1904 has been described by Souza in Brazil.

From a relatively obscure disease, human psittacosis was suddenly raised to a malady of world wide interest in 1929 1930, when it appeared in twelve different countries and involved approximately 750 to 800 persons Careful inquiries by Roubakine (1930), by Elkeles and Barros (1931), and by Barros (1940) indicate that South American parrots were the main source of the infection and that the world wide distribution sprang from an epizootic among parrots in Brazil (for details, see Meyer, 1942). With the discovery by Meyer and Eddie in 1931 and 1932 of the prevalence of latent psittacosis in local breeding establishments and aviaries in California, observations later confirmed in Canada, Germany, Austria, Holland, and England, the endemicity and the independence of the disease from imported birds were established Evidence furnished by Meyer and Eddie, and later by Burnet, conclusively proved the existence of psittacosis in wild Australian parakeets, parrots, lorikeets, and cockatoos Canaries and finches are proved sources of human infections Later, it was further recognized that the bird to man infection chain does not depend solely on parrots and parakeets Viral agents morphologically indistinguishable from psittacosis have been demonstrated in fulmars and petrels (*Fulmar glacialis*) by Haagen and Mauer (1939), in pigeons by Coles (1941), Meyer, Eddie, and Yanamura (1942), Smadel, Wall, and Gregg (1943), and Labzoffsky (1947), in chickens by Meyer and Eddie (1942), and in Pekin ducks and sea gulls by Eddie and Meyer (1947) The infection spectrum thus far known is exceedingly broad, and spontaneous parasitism by the viral agents in many different birds and even mammals may be anticipated

It was not until the 1929 1930 pandemic that Lillie (1930) in the United States, the British microscopist Coles (1930), and Levinthal (1930) in Germany discovered the minute viral bodies in exudates, blood, and organs of human beings, birds, and experimentally infected mammals In rapid succession, Krumwiede and associates, Armstrong and McCoy in the United States, Bedson and Western in England, Levinthal in Germany, and Sacquépée in France established the disease agent as a filtrable virus, while subsequent studies by Bedson (1930), Gordon (1930), and Bedson and Bland (1932) definitely confirmed the etiologic relationship The discovery by Krumwiede, McGrath, and Oldenbusch, that the virus is readily transmitted to white mice, enabled Bedson to demonstrate the morphologic cycle in mammalian tissues Propagation of virus in embryonated eggs by Burnet and Rountree (1935), and tissue culture technics devised by Bland and Canti (1935), Lazarus and Meyer (1939), and Yanamura and Meyer (1941) furnished antigens for immunologic studies and aided development of the complement fixation test. Demonstration of the viral agent in the sputum of patients by Rivers and Berry (1932 and 1935) advanced diagnostic technics A reproducible neutralization test enabled Hilleman (1945) to differentiate the antigenic relationship of avian and mammalian psittacosis viral agents Observations on a high person to person communicability of psittacosis like agents (Louisiana outbreak, Olson and Treuting, 1944) encourages the hypothesis that nonavian, possibly human strains may play a role in the ecology of the disease (Eaton et al, 1941, Meiklejohn, et al, 1944, Smadel, 1943, and Zichis and Shaughnessy, 1945) The study of human primary pneumonia not incurred by known bacteria has in recent years led to the discovery of viral agents indistinguishable from those causing psittacosis Additional psittacosis like viruses were isolated from the respiratory tract of both apparently healthy and diseased mammals The viruses which comprise this group are listed in the current literature under the following names: Miagawanella, meningopneumonitis virus, mouse pneumonitis virus, Australian mouse pneumonitis virus, feline pneumonitis virus, San Francisco (S F), the Illinois, and the Louisiana pneumonitis viruses (Reiman 1947)

CHAPTER 20

PSITTACOSIS (ORNITHOSIS, PSITACOSIS)

KARL F MEYER

DEFINITION

Psittacosis, although primarily an avian infection, occurs sporadically and in epidemics among human beings in many parts of the world It is an acute, specific disease, characterized in the early stages by high fever and but slight physical involvement, and later by patchy pneumonitis and severe toxemia It is caused by a viral agent (*Miyagawanella psittaci*) which primarily attacks reticuloendothelial cells It is acquired by exposure to psittacine birds, pigeons, ducks, chickens, and petrels

HISTORY

The first two cases of psittacosis were described by Jurgensen (1876) At Ulster, Switzerland, in 1879, Ritter described 7 cases of a peculiar acute pneumonia with 3 deaths, the outbreak coincided with the arrival of imported sick parrots in the vicinity He reported the disease by the clinically correct and descriptive title of "pneumo typhus" but emphasized that pneumonia and typhoid were not epidemic there at the time Autopsies on the birds were negative Similar observations were made at Bern in 1882 (Ost), at Leipzig in 1886 (Wagner), and at Bonn in 1887 A large outbreak (47 cases with 13 deaths) in Paris in 1892, which followed importation of parrots from Buenos Aires, was investigated by Dujardin Beaumetz, who concluded that it was of human origin since a certain number of patients apparently had no contact with the suspected birds, many of which showed no signs of illness The following year, Dubief established con clusively that a household outbreak of 5 cases, with 3 deaths was caused by contact with an infected parrot Strong support favoring the concept of a specific infection was gained through the work of Nocard, who fatally infected a healthy parrot by placing in its cage the dried wings of parrots involved in the Paris epidemic of 1892 He also isolated from the wings a gram negative, motile bacillus, Nocard s bacillus, which Gilbert and Fournier considered etiologically related to the parrot and human diseases. This organism, known as *Bacillus psittacosis*, is indistinguishable from *Salmonella typhimurium*, and was not dem onstrated in subsequent epidemics The name "psittacosis" (from the Latin *psittacus*, a parrot) was given by A Morange in 1895 in a thesis summarizing experiences with the disease in France.

The history of the disease in countries other than France is of interest Outbreaks in Italy were traced to importations of Amazon parrots In Germany (Dohringsdorf, 1892, and Krefeld, 1899) the human disease was observed to follow exposure to parakeets or lovebirds. The most important outbreak due to this species of the parrot family occurred at Zülpich (near Cologne) in 1909, when 2 apparently healthy parakeets infected their owners, 5 nurses, and 10 visitors who had congregated at the funeral of the husband Careful bacteriologic examination of a sacrificed parakeet yielded indifferent streptococci (Bachem, Selter, and Finkler, 1910) Direct contagion from person to person, although rare, was incontestably

EPIDEMIOLOGY

Geographic Distribution

Statistical data presented by Elkeles and Barros (1931), Haffenberg (1936), Barros (1940), Meyer (1943) and Meyer and Eddie (1947), although incomplete, fully attest to the worldwide distribution of psittacosis. Sporadic cases and household epidemics have been reported from Algeria, Argentina, Australia, Austria, Brazil, Canada, Czechoslovakia, Denmark, Egypt, England, France, Germany, Guatemala, Hawaiian Islands, Mexico, Netherlands, Poland, Portugal, San Salvador, Spain, Sweden, Switzerland and the United States. Excepting cases in Algeria traced to South American parrots, the disease has thus far remained unrecognized in Africa, despite at least one infection attributed to psittacine birds recently brought to England from West Africa. The mild, ambulatory or subclinical infections encountered with increasing frequency in recent years do not appear in current data but are numerous. A tabulation of official and nonofficial histories records for the period 1931-1946 in the United States 504 cases of psittacosis with *62 deaths*. During the early years of this period the majority of the infections (31 cases) were attributed to distribution and sale of locally bred and raised parakeets, but later restriction on importation of psittacine birds checked this source of infection. With the discovery of infectivity in fulmars, pigeons and chickens (1940) and more recently in ducks, several hundred human infections (186 fulmars, 103 pigeons and 5 ducks) have been traced to these birds. Epidemiologists all over the world must carefully investigate every avian and mammalian contact before inquiring into the possibility of human spreaders of virus.

Epidemic Features

The relative infrequency of human cases in Australia, Brazil, Argentina, Mexico and probably other Latin American countries, where avian psittacosis prevails among wild birds in the natural state, is not surprising in the light of newer knowledge on the natural history of the infection. The existence of epizootics among wild birds has been observed only in rare instances (Burnet and Parodi and Silvetti), since dead bodies are eaten by other animals or decompose. In birds infection originates from parents in the nest, and infected fledglings either suffer no symptoms or have overcome them by the time they are ready to fly. During the breeding period females suffer a transient activation of the infection and become shedders of the virus. This invisible cyclical spread in wild birds in the forests has little opportunity for transfer to human beings, but in domesticated birds its danger is apparent. Parrots are usually caught young, collected in depots and shipped to all parts of the world. There is ample documentation of birds becoming sick, dying and proving to be heavily infected with psittacosis a week or two after capture. Overcrowding in shipping cases, unsanitary conditions and change in climate provoke these mortalities and afford ample opportunity for spread of virus to man. Investigations on aviary bred parakeets and in pigeon lofts by Meyer and Eddie clarified the ecology of the host virus reactions. In an infected parakeet aviary, pigeon loft or zoological garden kept under the best sanitary conditions, the majority of adult birds appear healthy, although virus may be demonstrated in their spleens, livers and intestinal contents. Occasionally young birds may show signs of illness such as inactivity, loss of appetite, soiling of the vent and nasal discharge; a variable proportion may die. Overcrowding, overbreeding, uncleanliness and lack of care upset the balanced

is probably due to prolonged and frequent contact with infected birds in the closed rooms of a winter household. *It is well to emphasize, however, that* severe psittacosis on the Faroe Islands and among pigeon fanciers is not uncommon in midsummer and early fall. Observations indicate that the disease can be contracted throughout the year (Meyer, 1942).

Age, Sex, Race, and Occupation.—People of middle age, rarely children, are involved in the single or multiple case infections which develop in the same household. With the aid of the complement fixation test, Meyer and Eddie (1947) detected 15 juvenile cases of mild pneumonitis in a group of 111 persons handling pigeons, chickens, and parrots who gave positive reactions in diagnostically *significant titers*. *Thus while disposition is not confined to* older age groups, the likelihood of contracting the disease increases with age. The recent isolation of a psittacosis virus from the lung of a 14-year-old boy who handled birds further attests to the susceptibility of younger age groups.

There is a greater incidence of psittacosis in women than in men. The heavier distribution in women is ascribable to propinquity, that is, more women than men raise parakeets commercially or keep them as pets. Where the interest in the bird raising business has shifted to males, the likelihood *of infection and high case fatality rate are well documented. In the outbreak* at Cordoba, Spain, which followed auctioning of highly infected birds by male traders and barterers, the ratio of males to females was 49:36 (Barros). That occupational psittacosis is quite common in persons engaged in the breeding, raising, care, transportation, and sale of psittacine birds, pigeons, and ducks has not been accepted by all, although published records amply attest to its existence (Meyer, 1942 and 1943). The apparent immunity of men and women *continuously exposed to heavily infected parakeets, parrots, or pigeons* is in part attributable to subclinical infections. Limited serologic surveys among employees in aviaries, pigeon lofts, and zoological gardens lend support to this interpretation of epidemiologic observations. A survey of 110 cases in California revealed that 45, or nearly 40 per cent, were owners of parakeet aviaries or pigeon lofts, or that members of their families were. *During the* height of experimental investigations of psittacosis in 1929 and 1930, 38 laboratory infections were *contracted. Despite the institution of precautionary* measures, an additional 17 cases with 2 deaths have occurred in Germany, Argentina, and the United States since 1934.

Human Case to Case Infection.—Older observations and new reports show the increasing frequency of human case to case infections. In at least 23 instances involving 30 nurses, contact with sick birds was definitely excluded. Twice repeated human to human passage has been seen by Haagen and Kruckeberg (1937), and a chain transmission *in the third generation* has been reported by Hamre. A physician contracted the disease from a fatal case and was visited by an intern who developed psittacosis and recovered, but who, while ill, infected his nurse, who died; she in turn had transmitted the virus to a second nurse. More disconcerting are the transmissions which have oc-

immunity in the individual birds and favor epizootics Enormous masses of virus are dispersed by sick and dying birds providing a means of spread to owners ultimate purchasers or other contacts How long psittacine birds or pigeons are infective is not definitely known but epidemiologic and laboratory observations leave little doubt that they may carry or intermittently shed virus for years

Fleeting or prolonged exposure in a room house pet store aviary breeding establishment pigeon loft or barnyard where visibly diseased or apparently healthy parrots parakeets canaries pigeons ducks or chickens are kept may result in human infections Usually the responsible birds have been recently acquired In the past single cases escaped detection and the reports deal principally with the well known house epidemics which gave the epidemiology of psittacosis its characteristic stereotyped pattern Apart from its epidemiologic interest this feature of the disease is of diagnostic value especially in differentiating psittacosis from influenza which is more pandemic and rarely appears in localized outbreaks The handling of feathers from parrots or the cleaning of dead fulmars pigeons chickens and ducks have been responsible for infections Removal of manure from pigeon lofts is not infrequently followed by human psittacosis

Mode of Transmission

The mode of transmission of the avian virus to man is manifold (1) Direct contact with the diseased birds or objects fouled by excreta is the most common mode of transmission (2) Indirect transfer by air played an important role in the Zulpich epidemic in the cases reported by Horder and Gow (1930) and in the outbreak at the National Institute of Health (McCoy 1931) (3) Bite wounds may initiate infection (Faulscher et al 1945) The dispersion of the viral agent adherent to *desiccated fecal droppings may be* readily demonstrated in sentinel experiments with Java sparrows as advocated by Meyer (1942) Furthermore the ease with which inhalation of virus induces pneumonic lesions in susceptible mammals amply attests to the respiratory tract as the principal portal of entry for the virus Finally the main burden of infection in human cases falls on the respiratory tract lobular distribution of the pneumonic consolidation and inflammation of the mucosa of the upper respiratory tract are constant features of cases that come to autopsy

DISTRIBUTION AND PREVALENCE

Distribution is world wide Statistical data however must be considered approximations which deal with frank clinical cases No attempt has been made to secure information concerning the subclinical or mild cases often suspected but only occasionally proved serologically which have been encountered with increasing frequency in recent years

Seasonal Incidence The great epidemics of the past occurred during the winter and in Germany and Argentina the predominance of the disease at that time of the year (January to April) is striking The phenomenon

is probably due to prolonged and frequent contact with infected birds in the closed rooms of a winter household It is well to emphasize, however, that severe psittacosis on the Faroe Islands and among pigeon fanciers is not uncommon in midsummer and early fall Observations indicate that the disease can be contracted throughout the year (Meyer, 1942)

Age, Sex, Race, and Occupation—People of middle age, rarely children are involved in the single or multiple case infections which develop in the same household With the aid of the complement fixation test Meyer and Eddie (1947) detected 17 juvenile cases of mild pneumonitis in a group of 111 persons handling pigeons chickens and parrots who gave positive reactions in diagnostically significant titers Thus while disposition is not confined to older age groups the likelihood of contracting the disease increases with age The recent isolation of a psittacosis virus from the lung of a 14 year old boy who handled birds further attests to the susceptibility of younger age groups

Human Case to Case Infection—Older observations and new reports show the increasing frequency of human case to case infections In at least 23 instances involving 0 nurses contact with sick birds was definitely excluded Twice repeated human to human passage has been seen by Haagen and Kruckeberg (1937) and a chain transmission in the third generation has been reported by Hamre A physician contracted the disease from a fatal case and was visited by an intern who developed psittacosis and recovered but who while ill infected his nurse who died she in turn had transmitted the virus to a second nurse More disconcerting are the transmissions which have oc

curred in hospitals. In an epidemic in Buenos Aires reported by Loizaga and Averbach (1945), interhuman contagion was a striking feature of the outbreak, extending at times to the third passage. The experience detailed by Eaton, Beck, and Pearson (1941) illustrates the infectiousness of a man who transmitted psittacosis to 3 nurses. The 1943 epidemic of a severe pneumonitis in the Bayou region of Louisiana in which there were 8 deaths in 19 recognized infections among nursing attendants late (48 hours before death) in the illness of fatal cases, emphasizes the importance of direct contact in human to human transmission (Treuting and Olson 1944). Statistics such as these should serve to remind physicians that the occupational hazard to themselves and to nurses is considerable.

ETIOLOGY

The Causative Organism

The infective agent of psittacosis in birds and man is an obligatory intracellular parasite. It is specific and forms particulate elementary bodies. The agent develops in the cytoplasm of the reticuloendothelial cells in tissue cultures of mesenchyme cells in fibroblasts, and in epidermis epithelial and liver cells or cells derived from all three embryonic layers (Yanamura and Meyer 1941). On the basis of morphologic and antigenic similarities, psittacosis agents and those of lymphogranuloma venereum of man and of mouse and feline pneumonitis have been placed in a group intermediate between the rickettsiae and the true filtrable viruses.

The viral agent common to the group is an infective spherical or hemispherical—not rod shaped—elementary body tinctorially demonstrable with basic dyes. The infective bodies are usually 300 to 450 millimicrons in size and are held back partially or completely by the usual filters. They are readily propagated in the yolk sac of the embryonated hen's egg and in tissue cultures. They are agglutinated by specific antisera and serve as antigens in diagnostic complement fixation tests. They generate protective antibodies in birds and mammals including man. Moshkovsky (1945) has suggested the name *Miyagawanella psittaci* for the agent and has grouped it in the family of the Chlamydozoaceae.

Morphology and Staining Reactions

In microscopic preparations thin films made from plastic exudates and stained with Giemsa solution or preferably according to the method of Macchiavello the elementary bodies appear as purplish dark red or blue spherical structures singly or in pairs. In tissue cultures or in material from yolk sacs they increase rapidly in size and become embedded in a homogeneous ground substance or matrix. These initial bodies at first divide into elements of comparable size but as multiplication progresses the elements of division become smaller and smaller until the final elementary body stage is reached (Bland and Canti, 1935). Yanamura and Meyer (1941) *by relating morphologic findings in films and sections to the intervals* of the dynamic time sequence in tissue cultures established the following cycle of development.

One or more elementary bodies which are red when tinged according to Macchiavello or black purple according to Castañeda invade a cell and incite (if the cell is healthy) the formation of a single common matrix. If the virus particles disperse at opposite ends of a cell, each group may be surrounded by a separate matrix thus inducing double or triple infection foci within one cell. These forms correspond to the "plaques" of Bland and Canti, or to the "inclusion bodies" of Levinthal. The matrix of the homogeneous inclusion bodies stains blue green according to Macchiavello and since it is not densely colored the early virus particles are readily identified in increasing numbers. These large forms, measuring 2 to 12 microns

appear 18 to 24 hours after infection As the matrix becomes less dense, tinctorial differences become apparent *The larger virus particles are stained blue*, while the smaller forms (0 3 to 0 4 micron) are red

Electron photographs suggest that the elementary bodies contain a large amount of water and show two components a dense substance, usually *centrally located*, and a thinner, surrounding substance, which *appears to represent a limiting membrane from which the* central mass retracts (Hamre, Rake, and Rake 1947)

Some elementary bodies have a sticky substance on their surfaces, and it is not unlikely that this is responsible *for the different tinctorial reactions* *In living preparations, the* initial particles immobile in the originally rigid homogeneous inclusion bodies, increase in motility until finally in the flexible virus colony they undergo rapid oscillatory (Brownian) movement *This change more or less coincides with the conversion from blue to red staining* reactions The inclusion body is always surrounded by a definite membrane which persists even when in multiple infections one or two colonies coalesce Free dispersal of the elements *of a colony through the cytoplasm is rarely observed.*

At the forty eighth hour the matrix of the inclusion body presents evidences of liquefaction By that time, the elementary bodies which stain deeply red in Macchiavello preparations *have become so numerous that they may pack the cytoplasm* *Death of the host cell and* autolysis of the colony releases myriads of particulate elementary bodies, which are capable of invading and repeating the cycle in new cells

Levinthal s observation, that in damaged cells the virus multiplies without a definite matrix formation, is readily demonstrated in agar tissue cultures in which the embryonic cells are merely in a state of functional survival The time required for completion of the *developmental cycle is much shorter* *Large and small elementary bodies divide and multiply* to enormous numbers in the cytoplasm of highly vacuolated cells In prepartions stained by the Giemsa method the membrane is quite distinct, although no matrix can be demonstrated. *Filtration tests (Lazarus and Meyer, 1939) through collodion membranes and recent* electron micrographs by Kurotchkin et al (1947) established the mean diameter of the elementary bodies as 455 mμ ± 78 mμ The size of the feline pneumonitis virus in gold shadowed preparations *is reported as 525 mμ ± 84 mμ* (Hamre et al, 1947)

The initial bodies in the plaques are always larger than the parent organisms and, according to Bedson and Bland, are low in virulence, since they apparently encounter difficulties *in entering into cells* That the cytoplasmic plaques or inclusion bodies are true virus colonies made up of elementary bodies is conclusively established Merely the exact nature of the matrix remains uncertain Although findings in tissue cultures strongly incriminate it *as a product of the cytoplasm*, it is recalled that Findlay (1938) suggested that it may conceivably originate as a secretory product from the elementary bodies

Cultivation and Propagation

Psittacosis viruses are readily grown in media of the Maitland, La Rivers, and the Zinsser Fitzpatrick Wei agar tissue types (Yanamura and Meyer, 1941) More recently the roller tube tissue technic has come into use (Morgan and Wiseman, 1946) Chorio allantoic, amniotic, allantoic, and yolk inoculations in chick embryos are continuously employed for the preparation of highly infective suspensions which are used for serologic and immunologic studies and routine examinations (*for details, consult Beveridge and Burnet, 1946*)

Resistance to Physical and Chemical Environment

Prolonged centrifugation—6 to 8 hours—at 15 000 r p m has been shown to deposit the major portion of the virus Exposure to 56° C for 30 minutes does not completely destroy virus in mammalian organs Chick embryo virus is readily inactivated at 60° C for 10 minutes Crude heavy suspensions in broth may remain infectious at ±4° C for several weeks, but preparations of elementary bodies in buffered saline are noninfectious 29 days after preparation and storage Frozen at −70° C, the virus remains active for over 2 years

curred in hospitals In an epidemic in Buenos Aires reported by Loizaga and Averbach (1945), interhuman contagion was a striking feature of the outbreak, extending at times to the third passage The experience detailed by Eaton, Beck, and Pearson (1941) illustrates the infectiousness of a man who transmitted psittacosis to 3 nurses The 1943 epidemic of a severe pneumonitis in the Bayou region of Louisiana, in which there were 8 deaths in 19 recognized infections among nursing attendants late (48 hours before death) in the illness of fatal cases emphasizes the importance of direct contact in human to human transmission (Treuting and Olson 1944) Statistics such as these should serve to remind physicians that the occupational hazard to themselves and to nurses is considerable

They are agglutinated by specific antisera and serve as antigens in diagnostic complement fixation tests They generate protective antibodies in birds and mammals including man Moshkovsky (1945) has suggested the name *Miyagawanella psittaci* for the agent and has grouped it in the family of the Chlamydozoaceae

Morphology and Staining Reactions

In microscopic preparations, thin films made from plastic exudates and stained with Giemsa solution or preferably according to the method of Macchiavello the elementary bodies appear as purplish dark red or blue spherical structures singly or in pairs In tissue cultures or in material from yolk sacs they increase rapidly in size and become embedded in a homogeneous ground substance or matrix These initial bodies at first divide into elements of comparable size but as multiplication progresses, the elements of division become smaller and smaller until the final elementary body stage is reached (Bland and Canti, 1935) Yanamura and Meyer (1941) by refating morphologic findings in films and sections to the intervals of the dynamic time sequence in tissue cultures established the following cycle of development

One or more elementary bodies which are red when tinged according to Macchiavello or black purple according to Castañeda invade a cell and incite (if the cell is healthy) the formation of a single common matrix If the virus particles disperse at opposite ends of a cell, each group may be surrounded by a separate matrix thus indicating double or triple infection foci within one cell These forms correspond to the plaques of Bland and Canti, or to the inclusion bodies of Levinthal The matrix of the homogeneous inclusion bodies stains blue green according to Macchiavello and since it is not densely colored, the early virus particles are readily identified in increasing numbers These large forms, measuring 2 to 12 microns

appear 18 to 24 hours after infection As the matrix becomes less dense tinctorial differences become apparent The larger virus particles are stained blue, while the smaller forms (0.3 to 0.4 micron) are red

Electron photographs suggest that the elementary bodies contain a large amount of water and show two components a dense substance, usually centrally located, and a thinner, surrounding substance which appears to represent a limiting membrane from which the central mass retracts (Hamre, Lake and Rake, 1947)

Some elementary bodies have a sticky substance on their surfaces and it is not unlikely that this is responsible for the different tinctorial reactions In living preparations, the initial particles immobile in the originally rigid homogeneous inclusion bodies, increase in motility until finally in the flexible virus colony they undergo rapid oscillatory (Brownian) movement This change more or less coincides with the conversion from blue to red staining reactions. The inclusion body is always surrounded by a definite membrane which persists even when in multiple infections one or two colonies coalesce Free dispersal of the elements of a colony through the cytoplasm is rarely observed

At the forty-eighth hour the matrix of the inclusion body presents evidences of liquefaction By that time the elementary bodies which stain deeply red in Macchiavello preparations have become so numerous that they may pack the ectoplasm Death of the host cell and autolysis of the colony releases myriads of particulate elementary bodies, which are capable of invading and repeating the cycle in new cells.

Levinthal's observation, that in damaged cells the virus multiplies without a definite matrix formation, is readily demonstrated in agar tissue cultures, in which the embryonic cells are merely in a state of functional survival The time required for completion of the developmental cycle is much shorter Large and small elementary bodies divide and multiply to enormous numbers in the cytoplasm of highly vacuolated cells. In prepartions stained by the Giemsa method the membrane is quite distinct, although no matrix can be demonstrated. Filtration tests (Lazarus and Meyer, 1939) through collodion membranes and recent electron micrographs by Kurotchkin et al (1947) established the mean diameter of the elementary bodies as 475 mμ ± 78 mμ. The size of the feline pneumonitis virus in gold shadowed preparations is reported as 545 mμ ± 81 mμ (Hamre et al 1947)

The initial bodies in the plaques are always larger than the parent organisms and, according to Bedson and Bland, are low in virulence, since they apparently encounter difficulties in entering into cells That the cytoplasmic plaques or inclusion bodies are true virus colonies made up of elementary bodies is conclusively established Merely the exact nature of the matrix remains uncertain Although findings in tissue cultures strongly incriminate it as a product of the cytoplasm, it is recalled that Findlay (1938) suggested that it may conceivably originate as a secretory product from the elementary bodies

Cultivation and Propagation

Psittacosis viruses are readily grown in media of the Maitland, Li Rivers and the Zinsser Fitzpatrick Wei agar tissue types (Yanamura and Meyer, 1941) More recently the roller tube tissue technic has come into use (Morgan and Wiseman 1946) Chorio allantoic amniotic, allantoic and yolk inoculations in chick embryos are continuously employed for the preparation of highly infective suspensions which are used for serologic and immunologic studies and routine examinations (for details, consult Beveridge and Burnet 1946)

Resistance to Physical and Chemical Environment

Prolonged centrifugation—6 to 8 hours—at 15,000 r.p.m has been shown to deposit the major portion of the virus Exposure to 56° C for 30 minutes does not completely destroy virus in mammalian organs Chick embryo virus is readily inactivated at 60° C for 10 minutes. Crude heavy suspensions in broth may remain infectious at +4° C for several weeks, but preparations of elementary bodies in buffered saline are noninfectious 29 days after preparation and storage Frozen at -70° C, the virus remains active for over 2 years

In 50 per cent glycerin in buffered saline at pH 7 6 and at ±4° C., heavy suspensions retain their activity for 10 to 20 days Sputums and human lung specimens rapidly lose their potency in glycerin Formalin, 0 1 per cent, and phenol, 0 5 per cent, in activate the psittacosis virus in 24 to 36 hours, while 10 per cent ether at room temperature destroys it within 30 minutes on heavy chick embryo suspensions or in agar tissue cultures

Toxin

According to Rake and Jones (1944), yolk sacs infected with the meningopneumonitis virus of Francis and Magill and shaken with amniotic and allantoic fluid are toxic to mice on intravenous or intraperitoneal injection This toxin is labile and is not readily separated from the elementary bodies Specific antitoxins produced in rabbits and chickens are ef fective against a few lethal doses of it Many of the lesions observed in animals infected with the Louisiana virus bear signs of toxemia.

Virulence

Psittacosis viruses isolated from different species of animals, and from man, vary con siderably in their effects on mice Strains of proved pigeon or duck origin produce irregu lar mortalities in white mice on intraperitoneal inoculation. It is claimed that some strains which are adapted to human beings lose their pathogenicity for mice and birds, latent in fections are demonstrable only up to 21 days by subinoculation (Meiklejohn et al, 1944)

Antigenic Structure

In 1936, Bedson found that psittacosis virus, which he used as a reagent in the comple ment fixation test, contained at least two important antigens one, heat labile, was destroyed by temperatures above 60° C, while the other could withstand boiling As a result of infec tion, antibodies to both antigens are produced, the latter in considerably greater quantity Although the role of the antibodies to heat stable antigens in immunity to psittacosis serum is not known, they constitute a reliable index of infection The heat stable antigen is also ether soluble, and in all probability is common to the protein molecule of all viruses in the lymphogranuloma psittacosis group Infected yolk sacs or mouse spleen suspensions treated with phenol, then boiled and centrifuged, yield clear supernatant fluids, which produce al lergic reactions in sensitized guinea pigs and suggestive precipitin reactions with specific antisera. Nothing definite is known about the antigens, which give rise to species specific antibodies responsible for the highly specific protection against different members of the lymphogranuloma psittacosis group, or of the neutralization of toxins (Hilleman, 1945)

Distribution in the Body and Routes of Escape

Through inoculations of parakeets (Bedson, 1930) and mice (Eddie and Meyer, 1947), blood from patients tested during the first two weeks of the disease has been repeatedly found to contain the virus It was Coles (1930 who first observed elementary bodies in sera from pa tients Sputum (up to and including the twenty sixth day) and occasionally throat gargling and vomitus may yield the infective agent in animal tests At autopsy, virus is readily de monstrable in the pleural exudates, pneumonic lesions, spleens, and livers of human beings It has been regularly isolated in exudates, blood, livers, spleens, kidneys, intestinal and cloacal contents, and urine from parrots, pigeons, and ducks The virus escapes from the body of birds and mice via the intestinal and nasal discharges. In latent infection of birds, virus is confined to the spleen and liver, irregularly to the intestinal contents Numerous investigators have seen viral bodies in man in the epithelial lining of the pulmonary alveoli, in the liver, the Kupffer cells, and in macrophage cells of splenic sinuses With the aid of the differential staining method of Noble, which reveals red elementary bodies against a green background, viral elements are readily seen in nearly every organ of animals and birds dead of psittacosis.

SUSCEPTIBLE ANIMALS

(1) Mammals

For the isolation of the virus, the mouse may be infected by the intraperitoneal, intravenous, subcutaneous, intranasal, and intracerebral routes and by feeding. Death may occur in 3 to 30 days, with an average of 6 to 10 days. Some mice will recover or latent infection may persist for 10 to 12 months (Meyer and Eddie, 1933, and Bedson, 1938). When death has occurred 2 to 4 days after inoculation, autopsy shows the abdominal viscera covered by a thin sticky exudate, *with endothelial cells and leucocytes packed with elementary bodies.* When death occurs 10 to 20 days after inoculation, the viscera are coated with a thick layer of film; the enlarged liver shows marginal necrosis, and the spleen is voluminous and soft. Mice with latent infections have enlarged spleens. Psittacosis virus administered intranasally produces widespread consolidation of either lobe of the lung. Discrete, grayish foci of pneumonia are manifested as the limiting infective dilutions of virus are approached (Rake and Burnet, 1941 and Hornus 1940).

With the exception of *feline strains* and certain murine strains (Grebb), most psittacosis viral agents injected intracerebrally cause irritability, motor hyperactivity, ataxia, convulsive seizure, and death within 3 to 6 days. Microscopically, the meningoencephalitis is characterized by an exudate of polymorphonuclear and mononuclear cells, which extends along the blood vessels into the brain. The cellular elements are usually very rich in viral bodies (Gordon, 1930, Rivers and Berry, 1931). In the *feeding* experiments reported by Fortner and Pfaffenberg (1934), a high percentage (78 per cent) of the mice succumbed to abdominal psittacosis, in 17 of 46 cadavers, pneumonic lesions were also found. Ingestion is apparently associated with inhalation of the virus.

Most strains of psittacosis are reported to have little visible effect on guinea pigs when inoculated intraperitoneally. They incite a prolonged febrile reaction. However, strains recently isolated in Louisiana (Olson and Larson, 1944-1945, Fite, Larson, and Olson, 1946) and California from human cases of pneumonitis are highly virulent for guinea pigs irrespective of inoculation routes. The intensity of the clinical illness depends on the dose given; anorexia, fever, listlessness, and loss of weight are followed by death within 4 to 10 days.

Some strains produce fatal meningoencephalitis in *rabbits* infected by the intracerebral route. *Pulmonary focal infiltrations and extensive pneumonic consolidations*, occasionally fatal, may be produced by intratracheal injection of virus (Rivers and Berry, 1931, and Morgan, 1946).

Monkeys are susceptible to intratracheal and intracerebral inoculations while intraperitoneal injections may produce no ill effects (Olson and Larson, 1945). Pocket gophers *(Thomomys bottae bottae)*, Syrian hamsters *(Cricetus auratus)*, cotton rats *(Sigmodon hispidus)*, and squirrels *(Citellus beecheyi)* are successfully infected by intranasal and intracranial routes.

(2) Birds

Reports from Australia and Argentina indicate that spontaneous psittacosis is common *among wild parrots, parakeets, and conures*, probably as a population regulator. At least 33 different species of the parrot family are known to be hosts to the virus. Common to all is a high incidence of prolonged latent infection, which is frequently responsible *for introducing the disease to finches and canaries in bird shops* and aviaries. High mortalities in importations (Meyer and Eddie, 1939, and Dunnahoo and Hampton, 1945) or outbreaks in zoological gardens (Burnet, 1935, Troup, Adam, and Bedson, 1939, and Tomlinson, 1941) follow crowding in unsanitary cages or exposure to low temperature, which induces relapses in latent infections. Enormous virus dispersal rapidly spreads the infection from diseased to susceptible birds. A variable number may die but a great many carriers develop.

In 50 per cent glycerin in buffered saline at pH 7.6 and at ±4° C., heavy suspensions retain their activity for 10 to 20 days. Sputums and human lung specimens rapidly lose their potency in glycerin. Formalin, 0.1 per cent, and phenol, 0.5 per cent, inactivate the psittacosis virus in 24 to 36 hours, while 10 per cent ether at room temperature destroys it within 30 minutes on heavy chick embryo suspensions or in agar tissue cultures.

Toxin

According to Rake and Jones (1944), yolk sacs infected with the meningopneumonitis virus of Francis and Magill and shaken with amniotic and allantoic fluid are toxic to mice on intravenous or intraperitoneal injection. This toxin is labile and is not readily separated from the elementary bodies. Specific antitoxins produced in rabbits and chickens are effective against a few lethal doses of it. Many of the lesions observed in animals infected with the Louisiana virus bear signs of toxemia.

Virulence

Psittacosis viruses isolated from different species of animals, and from man, vary considerably in their effects on mice. Strains of proved pigeon or duck origin produce irregular mortalities in white mice on intraperitoneal inoculation. It is claimed that some strains which are adapted to human beings lose their pathogenicity for mice and birds; latent infections are demonstrable only up to 21 days by subinoculation (Meiklejohn et al., 1944).

Antigenic Structure

In 1936, Bedson found that psittacosis virus, which he used as a reagent in the complement fixation test, contained at least two important antigens: one, heat labile, was destroyed by temperatures above 60° C., while the other could withstand boiling. As a result of infection, antibodies to both antigens are produced, the latter in considerably greater quantity. Although the role of the antibodies to heat-stable antigens in immunity to psittacosis serum is not known, they constitute a reliable index of infection. The heat-stable antigen is also ether soluble, and in all probability is common to the protein molecule of all viruses in the lymphogranuloma-psittacosis group. Infected yolk sacs or mouse spleen suspensions treated with phenol, then boiled and centrifuged, yield clear supernatant fluids, which produce allergic reactions in sensitized guinea pigs and suggestive precipitin reactions with specific antisera. Nothing definite is known about the antigens, which give rise to species-specific antibodies responsible for the highly specific protection against different members of the lymphogranuloma-psittacosis group, or of the neutralization of toxins (Hilleman, 1945).

Distribution in the Body and Routes of Escape

Through inoculations of parakeets (Bedson, 1930) and mice (Eddie and Meyer, 1947), blood from patients tested during the first two weeks of the disease has been repeatedly found to contain the virus. It was Coles (1930) who first observed elementary bodies in sera from patients. Sputum (up to and including the twenty-sixth day) and occasionally throat garglings and vomitus may yield the infective agent in animal tests. At autopsy virus is readily demonstrable in the pleural exudates, pneumonic lesions, spleens, and livers of human beings. It has been regularly isolated in exudates, blood, livers, spleens, kidneys, intestinal and cloacal contents, and urine from parrots, pigeons, and ducks. The virus escapes from the body of birds and mice via the intestinal and nasal discharges. In latent infection of birds, virus is confined to the spleen and liver, irregularly to the intestinal contents. Numerous investigators have seen viral bodies in man in the epithelial lining of the pulmonary alveoli, in the liver, the Kupffer cells, and in macrophage cells of splenic sinuses. With the aid of the differential staining method of Noble, which reveals red elementary bodies against a green background, viral elements are readily seen in nearly every organ of animals and birds dead of psittacosis.

SUSCEPTIBLE ANIMALS

(1) Mammals

For the isolation of the virus, the mouse may be infected by the intraperitoneal, intravenous, subcutaneous, intranasal, and intracerebral routes and by feeding. Death may occur in 3 to 30 days with an average of 6 to 10 days. Some mice will recover or latent infection may persist for 10 to 12 months (Meyer and Eddie, 1933 and Bedson, 1938). When death has occurred 2 to 4 days after inoculation, autopsy shows the abdominal viscera covered by a thin sticky exudate with endothelial cells and leucocytes packed with elementary bodies. When death occurs 10 to 20 days after inoculation, the viscera are coated with a thick layer of fibrin; the enlarged liver shows marginal necroses, and the spleen is voluminous and soft. Mice with latent infections have enlarged spleens. Psittacosis virus administered intranasally produces widespread consolidation of the lung. Discrete, grayish foci of pneumonia are manifested as the limiting infective dilutions of virus are approached (Bull and Burnet, 1941 and Hornus 1940).

With the exception of feline strains and certain murine strains (Grell), most psittacosis viral agents injected intracerebrally cause irritability, motor hyperactivity, ataxia, convulsive seizure and death within 3 to 6 days. Microscopically, the meningo-encephalitis is characterized by an exudate of polymorphonuclear and mononuclear cells which extends along the blood vessels into the brain. The cellular elements are usually very rich in viral bodies (G[illegible]n, [illegible]; Rivers and Berry, 1931). In the *feeding* experiments reported by [illegible]rtner and Pfaffenberg (1934), a high percentage (78 per cent) of the mice succumbed to abdominal psittacosis; in 17 of 46 cadavers pneumonic lesions were also found. Ingestion is apparently associated with inhalation of the virus.

Most strains of psittacosis are reported to have little visible effect on *guinea pigs* when inoculated intraperitoneally. They incite a prolonged febrile reaction. However, strains recently isolated in Louisiana (Olson and Larson, 1944, 1945; Fite, Larson and Olson, 1946) and California from human cases of pneumonitis are highly virulent for guinea pigs irrespective of inoculation routes. The intensity of the clinical illness depends on the doses given; an texia, fever, listlessness and loss of weight are followed by death within 4 to 10 days.

Some strains produce fatal meningoencephalitis in *rabbits* infected by the intracerebral route. Pulmonary focal infiltrations and extensive pneumonic consolidations, occasionally fatal, may be produced by intratracheal injection of virus (Rivers and Berry 1931 and Morgan 1946).

Monkeys are susceptible to intratracheal and intracerebral inoculations, while intraperitoneal injections may produce no ill effects (Olson and Larson, 1945). Pocket gophers *(Thomomys bottae bottae)*, Syrian hamsters *(Cricetus auratus)*, cotton rats *(Sigmodon hispidus)* and squirrels *(Citellus beecheyi)* are successfully infected by intranasal and intracranial routes.

(2) Birds

Reports from Australia and Argentina indicate that spontaneous psittacosis is common among wild parrots, parakeets and conures, probably as a population regulator. At least 33 different species of the parrot family are known to be hosts to the virus. Common to all is a high incidence of prolonged latent infection which is frequently responsible for introducing the disease to finches and canaries in bird shops and aviaries. High mortalities in importations (Meyer and Eddie 1939, and Dunnahoo and Hampton 1945) or outbreaks in zoological gardens (Burnet 1935, Troup, Adam and Bedson 1939 and Tomlinson 1941) follow crowding in unsanitary cages or exposure to low temperature which induces relapses in latent infections. Enormous virus dispersal rapidly spreads the infection from diseased to susceptible birds. A variable number may die but a great many carriers develop.

The clinical disease in different species of parrots, parakeets or conures infected with psittacosis virus is not characteristic. Autopsies and laboratory examinations are imperative to prove the nature of the disease. Far reaching is the discovery that visibly "healthy" birds harbor the virus and as shedders, disseminate the organisms. Psittacosis among finches in the wild has not been reported. Canaries as well as finches are aberrant hosts which acquire infection, as a rule, from exposure to diseased parakeets or parrots or through seeds contaminated by droppings of these species (see Meyer 1942).

The observations of Coles (1940), Meyer et al (1942), Smadel et al (1943 and 1945), Andrewes and Mills (1943) and [illegible]alzoffsky (1947) prove a wide distribution of psittacosis in the *pigeon* lofts of the United States, Canada, South Africa and Great Britain. Complement fixation tests seem to indicate that the majority of the birds are infected as squabs, and latency of the virus may be demonstrated in at least 10 to 20 per cent of the pigeons. Relatively few acute, spontaneous infections uncomplicated by salmonellosis or by other viruses have been studied, however, epizootics have been described (Smadel et al.). *Chickens (Gallus gallus)* have been found to carry virus in their organs and cloacal contents when in contact with pigeons (see Meyer 1943). Recent studies by Eddie and Meyer have proved the existence of acute and chronic psittacosis among *Pekin ducks* (Anasplatyrhynchos) commercially bred and raised in California and on Long Island. Extent of the disease in fulmars or petrels *(Fulmar glacialis)* on the Faroe Islands and in Iceland is unknown (Haagen and Mauer, 1939, and Bedson, 1940). Parakeets *(Melopsittacus undulatus)*, Amazon parrots *(Amazona festiva, Amazona aestiva)*, parrotlets *(Forpus passerinus)*, African lovebirds *(Agapornis personata)*, and green paroquets *(Myiopsitta monachus)* readily acquire psittacosis by exposure in cages or by inoculation. Loss of weight, weakness, watery stools, and nasal discharges are observed during the course of the disease, which in a fair percentage may not be fatal. Autopsy findings reveal a seropurulent coating on the walls of the air sac and the inner lining of the sternum. The liver is usually swollen, pale saffron to ocher colored, occasionally studded with small and large necrotic areas. The spleen is usually enlarged and sometimes spotted with fine necroses. The kidneys are swollen, grayish and soft. Only in rare instances are lesions demonstrable in the lung. In chronic infections the gross lesions are essentially negative except for a definitely enlarged spleen, thickening of the air sacs and scars of healed necroses in the liver. Ricebirds *(Munia oryzivora)*, canaries *(Serinus canaria)*, sparrows *(Zonotrichia and Passer domesticus)* and various finches *(Carpodacus mexicanus* [illegible] and *(*[illegible]*)* may be fatally infected by inoculation or exposure.

TRANSMISSION

Since no intermediate hosts and vectors have been established, the mode of virus transmission from bird to bird and from bird to man is relatively simple. Inhalation and, in aviaries, ingestion play the principal roles.

IMMUNITY

Individuals recovering from an attack of psittacosis are generally believed to be resistant to reinfection. Records of second infections are not numerous, but when the total experience with the disease is taken into consideration they are significant. Rasmussen (1938) reported two women patients who contracted the fulmar disease a second time. Wenckebach (1936) and Meyer (1939, 1940) have records of proved second attacks which may be interpreted as relapsing cases or as reinfection. Apparently the immunity is not absolute, and the residual virus held in certain tissues is not always in an innocuous equilibrium.

Another problem deserves consideration in connection with immunity to psittacosis. Persons who come in contact repeatedly with infected birds may

develop subclinical forms of the disease and possibly act as transient human carriers of infection (Gerlach, 1936).

Finally, a viral agent endowed with persistence in the tissues occasionally produces a chronic *carrier stage after recovery*. A patient who is still shedding virus in the sputum eight years after a severe psittacosis infection has recently been discovered by Meyer and Eddie (1947). Parrots, parakeets, pigeons, mice, guinea pigs, rabbits and monkeys which recover from one attack of psittacosis are usually resistant to a second inoculation.

To what extent immunity is dependent on latent infection has not been determined. Observations by Yanamura and Meyer (1942) on mice and Eddie and Meyer on monkeys and pigeons amply attest to the fact that immunity of the nonsterile type fails to operate when a relatively large superinfection is administered by the intracerebral or intranasal route. On the other hand it is equally well known *that guinea pigs which have recovered from an infection* and with organs free from psittacosis virus resist reinfection with massive doses of Louisiana virus. The ability of mice to acquire immunity and resist artificial infection is apparently determined by the genetic constitutions of individual animals. Following a relatively mild infection, some individuals acquire a low grade immunity protective against frank disease but not against persistent latent infection, while others develop an immunity which enables them to resist infection by destroying a dose of virus not exceeding 100 M.L.D. (*Yanamura and Meyer, 1941*). *Is it therefore not reasonable to consider that* the immunity of human beings recovered from psittacosis is in part dependent on genetic factors and on the relative dose of the viral agent to which they are exposed on reinfection?

Active immunity against psittacosis has been produced in mice by repeated inoculation *of viral suspensions inactivated by methylene blue or 0.2 per cent formalin. A considerable* degree of immunity has been conferred to rice birds and parakeets with formalin treated noninfective tissue culture antigens. Monkeys, guinea pigs, mice, rabbits and chickens have been *hyperimmunized with live virus; their sera have been found* to contain complement fixing, protective, and toxin neutralizing antibodies (see Hilleman, 1945). Immunizations of human volunteers against psittacosis have been carried out with dilutions of live virus subcutaneously administered (Rivers and Schwentker, 1934). Suspensions of infected mouse livers and spleens diluted 1:1,000 to 1:10, respectively, were given intramuscularly in 0.5 c.c. amounts in increasing concentrations at weekly intervals. No ill effects were observed and the sera were later shown to have developed neutralizing antibodies. The injection of antigens prepared from phenol killed, ether extracted yolk sac suspensions, if administered repeatedly in large amounts, likewise stimulates the production of antibodies in man. Antigens prepared from infected yolk sacs lyophilized before extraction and rich in elementary bodies protected 75 per cent of mice *following three abdominal injections against 1 to 10* M.L.D. by the respiratory or the intracerebral route (Wagner et al., 1946). Early reports on the question emphasized that neutralizing antibodies could not be demonstrated in the sera of convalescent cases of psittacosis. *By using a more delicate technic*, however, Rivers and Schwentker (1934) found that monkeys recovered from psittacosis pneumonia or vaccinated with live virus possessed neutralizing antibodies in their sera, but the titer was relatively low. *Some human beings with positive histories of psittacosis* possessed demonstrable neutralizing antibodies. Similar observations were made by Meyer and Eddie (1939) on sera from human patients, guinea pigs and birds hyperimmunized with live virus.

The clinical disease in different species of parrots, parakeets, or conures infected with psittacosis virus is not characteristic. Autopsies and laboratory examinations are imperative to prove the nature of the disease. Far reaching is the discovery that visibly "healthy" birds harbor the virus and, as shedders, disseminate the organisms. Psittacosis among finches in the wild has not been reported. Canaries, as well as finches, are aberrant hosts which acquire infection, as a rule, from exposure to diseased parakeets or parrots, or through seeds contaminated by droppings of these species (see Meyer, 1942).

The observations of Coles (1940), Meyer et al (1942), Smadel et al (1943 and 1945), Andrewes and Mills (1943), and Labzoffsky (1947) prove a wide distribution of psittacosis in the *pigeon* lofts of the United States, Canada, South Africa, and Great Britain. Complement fixation tests seem to indicate that the majority of the birds are infected as squabs, and latency of the virus may be demonstrated in at least 10 to 20 per cent of the pigeons. Relatively few acute, spontaneous infections uncomplicated by salmonellosis or by other viruses have been studied, however, epizootics have been described (Smadel et al.). *Chickens (Gallus gallus)* have been found to carry virus in their organs and cloacal contents when in contact with pigeons (see Meyer, 1943). Recent studies by Eddie and Meyer have proved the existence of acute and chronic psittacosis among *Pekin ducks* (Anasplatyrhynchos) commercially bred and raised in California and on Long Island. Extent of the disease in fulmars or petrels *(Fulmar glacialis)* on the Faroe Islands and in Iceland is unknown (Haagen and Mauer, 1939, and Bedson, 1940). Parakeets *(Melopsittacus undulatus)*, Amazon parrots *(Amazona festiva, Amazona aestiva)*, parrotlets *(Forpus passerinus)*, African lovebirds *(Agapornis personata)*, and green paroquets *(Myiopsitta monachus)* readily acquire psittasosis by exposure in cages or by inoculation. Loss of weight, weakness, watery stools, and nasal discharges are observed during the course of the disease, which in a fair percentage may not be fatal. Autopsy findings reveal a seropurulent coating on the walls of the air sac and the inner lining of the sternum. The liver is usually swollen, pale saffron to ocher colored, occasionally studded with small and large necrotic areas. The spleen is usually enlarged and sometimes spotted with fine necroses. The kidneys are swollen, grayish and soft. Only in rare instances are lesions demonstrable in the lung. In chronic infections, the gross lesions are essentially negative except for a definitely enlarged spleen, thickening of the air sacs, and scars of healed necroses in the liver. Ricebirds *(Munia oryzivora)*, canaries *(Serinus canaria)*, sparrows *(Zonotrichia* and *Passer domesticus)*, and various finches *(Carpodacus mexicanus, Poephila* and *Cyanospiza)* may be fatally infected by inoculation or exposure.

TRANSMISSION

Since no intermediate hosts and vectors have been established, the mode of virus transmission from bird to bird and from bird to man is relatively simple. Inhalation and, in aviaries, ingestion play the principal roles.

IMMUNITY

Individuals recovering from an attack of psittacosis are generally believed to be resistant to reinfection. Records of second infections are not numerous, but when the total experience with the disease is taken into consideration, they are significant. Rasmussen (1938) reported two women patients who contracted the fulmar disease a second time. Is it therefore not reasonable to consider that* the immunity of human beings recovered from psittacosis is in part dependent on genetic factors and on the relative dose of the viral agent to which they are exposed on reinfection?

[illegible]

The neutralization test, while not too reliable for diagnosing psittacosis, has, in the hands of Hilleman (1945), proved invaluable in the identification of members of the lymphogranuloma psittacosis group By intraperitoneal inoculation of chickens or rabbits, he prepared neutralizing antisera of relatively high titer and sharp specificity Serum virus mixtures are tested by intranasal or intracerebral inoculation of mice By means of cross serum neutralization tests, Hilleman, and, more recently, St John and Gordon (1947), observed that the pigeon pneumonitis and meningopneumonitis viruses of Francis and Magill are similar to each other and different from other agents of the group Mouse pneumonitis viruses proved to be similar, but different from all other agents The lymphogranuloma virus was found to differ from all other agents thus far tested. The protective effect of antisera on experimental infections has also been demonstrated by these tests

As early as 1930, Bedson had shown that the sera of psittacosis patients react specifically in *complement fixation tests* when brought in contact with infectious mouse spleen Improvements in antigen preparation by Bedson (1935 and 1936), Meyer and Eddie (1939), and Smadel, Wertman, and Reagan (1943) lead to the demonstration of complement fixing antibodies as early as the tenth day of the patient s illness, with increasing titers during convalescence Parrots and parakeets (Meyer and Eddie, 1939), recovered from psittacosis, develop antibodies that fix complement with psittacosis and lymphogranuloma antigens The sera of pigeons (Eddie and Francis, 1942) react only in the presence of psittacosis antigens In the course of active immunizations with live or dead virus, specific complement fixing antibodies are demonstrable in the sera of mice, guinea pigs, rabbits, and monkeys The complement fixation test is a useful aid in the survey of shipments of imported psittacine birds and flocks of pigeons Antibodies are present in the majority of these birds when in a latent state of infection, it is therefore the best tool for the quick survey of sources of infection

Bedson (1933), Lazarus and Meyer (1939), Hilleman (1943), and Labzoffsky (1946) have shown that the hyperimmune sera of guinea pigs, rabbits monkeys, and chickens *agglutinate* purified suspensions of elementary bodies in titers as high as 1 320 Agglutinins are, in fact, the only antibodies which besides protective properties, may be demonstrated in the sera of hyperimmune chickens and ducks Convalescent sera obtained from human beings contain agglutinins in diagnostically significant titers Studies by Meyer (1941) implicated phagocytic activity, possibly aided by humoral antibodies in the immunity process Heat stable psittacosis antigens produce definite *allergic cutaneous reactions* in guinea pigs, and occasionally in man (Wilches et al, 1946) Frei antigen fails to incite typical skin reactions in patients recovered from psittacosis or in carriers Antigens prepared from yolk sacs infected with meningopneumonitis or psittacosis virus produced skin reactions—erythema and induration—when injected intradermally into rabbits convalescent from respiratory meningopneumonitis infections (Morgan, 1947)

PATHOLOGY

The changes found at autopsy are those of a general septicemia with inflammatory processes in the lungs Detailed pathologic data may be found in Haedke (1898), Leichtenstern (1899), Oberndorfer (1930), Hutchinson, Rowlands, and Simpson (1930), Maclachlan Permar, and Rogers (1930), Peterson et al (1930), Sturdee and Scott (1930), Bortz and Green (1930), Scholte (1930), Polayes and Lederer (1932), Lillie (1933), Foord (1934), Mansens (1934), Haagen and Kruckeberg (1937), Barros (1940), Binford and Hauser (1944), and Tanner et al (1945) This mass of literature emphasizes the following findings

Lungs—The consolidated areas are readily palpable and are sharply demarcated from normal lung tissues They appear as gray or gray reddish,

develop subclinical forms of the disease and possibly act as transient human carriers of infection (Gerlach, 1936)

Finally, a viral agent endowed with persistence in the tissues occasionally produces a chronic carrier stage after recovery A patient who is still shedding virus in the sputum eight years after a severe psittacosis infection has recently been discovered by Meyer and Eddie (1947) Parrots parakeets pigeons, mice, guinea pigs rabbits, and monkeys which recover from one attack of psittacosis are usually resistant to a second inoculation

To what extent immunity is dependent on latent infection has not been determined Observations by Yanamura and Meyer (1942) on mice and Eddie and Meyer on monkeys and pigeons amply attest to the fact that immunity of the nonsterile type fails to operate when a relatively large superinfection is administered by the intracerebral or intranasal route On the other hand it is equally well known that guinea pigs which have recovered from an infection, and with organs free from psittacosis virus, resist reinfection with massive doses of Louisiana virus The ability of mice to acquire immunity and resist artificial infection is apparently determined by the genetic constitutions of individual animals Following a relatively mild infection some individuals acquire a low grade immunity protective against frank disease, but not against persistent latent infection while others develop an immunity which enables them to resist infection by destroying a dose of virus not exceeding 100 M L D (Yanamura and Meyer, 1941) Is it therefore not reasonable to consider that the immunity of human beings recovered from psittacosis is in part dependent on genetic factors and on the relative dose of the viral agent to which they are exposed on reinfection?

Active immunity against psittacosis has been produced in mice by repeated inoculation of viral suspensions inactivated by methylene blue or 0 ° per cent formalin A considerable degree of immunity has been conferred to ricebirds and parakeets with formalin treated noninfective tissue culture antigens Monkeys guinea pigs mice rabbits, and chickens have been hyperimmunized with live virus, their sera have been found to contain complement fixing, protective and toxin neutralizing antibodies (see Hilleman, 1945) Immunizations of human volunteers against psittacosis have been carried out with dilutions of live virus subcutaneously administered (Rivers and Schwentker, 1934) Suspensions of infected mouse livers and spleens diluted 1 1 000 to 1 10 respectively, were given intramuscularly in 0 5 c c amounts in increasing concentrations at weekly intervals No ill effects were observed, and the sera were later shown to have developed neutralizing antibodies. The injection of antigens prepared from phenol killed ether extracted yolk sac suspensions if administered repeatedly in large amounts, likewise stimulates the production of antibodies in man Antigens prepared from infected yolk sacs lyophilized before extraction and rich in elementary bodies protected 75 per cent of mice following three abdominal injections against 1 to 10 M L D by the respiratory or the intracerebral route (Wagner et al 1946) Early reports on the question emphasized that neutralizing antibodies could not be demonstrated in the sera of convalescent cases of psittacosis By using a more delicate technic, however, Rivers and Schwentker (1934) found that monkeys recovered from psittacosis pneumonia or vaccinated with live virus possessed neutralizing antibodies in their sera, but the titer was relatively low Some human beings with positive histories of psittacosis possessed demonstrable neutralizing antibodies Similar observations were made by Meyer and Eddie (1939) on sera from human patients guinea pigs, and birds hyperimmunized with live virus

The neutralization test, while not too reliable for diagnosing psittacosis, has, in the hands of Hilleman (1945), proved invaluable in the identification of members of the lymphogranuloma psittacosis group By intraperitoneal inoculation of chickens or rabbits, he prepared neutralizing antisera of relatively high titer and sharp specificity Serum virus mixtures are tested by intranasal or intracerebral inoculation of mice By means of cross serum neutralization tests Hilleman and, more recently, St John and Gordon (1947), observed that the pigeon pneumonitis and meningopneumonitis viruses of Francis and Magill are similar to each other and different from other agents of the group Mouse pneumonitis viruses proved to be similar, but different from all other agents The lymphogranuloma virus was found to differ from all other agents thus far tested The protective effect of antisera on experimental infections has also been demonstrated by these tests

As early as 1930, Bedson had shown that the sera of psittacosis patients react specifically in *complement fixation tests* when brought in contact with infectious mouse spleen Improvements in antigen preparation by Bedson (1935 and 1936) Meyer and Eddie (1939), and Smadel, Wertman, and Reagan (1943) lead to the demonstration of complement fixing antibodies as early as the tenth day of the patient s illness with increasing titers during convalescence Parrots and parakeets (Meyer and Eddie 1939) recovered from psittacosis, develop antibodies that fix complement with psittacosis and lymphogranuloma antigens The sera of pigeons (Eddie and Francis, 1942) react only in the presence of psittacosis antigens In the course of active immunizations with live or dead virus, specific complement fixing antibodies are demonstrable in the sera of mice guinea pigs rabbits and monkeys The complement fixation test is a useful aid in the survey of shipments of imported psittacine birds and flocks of pigeons Antibodies are present in the majority of these birds when in a latent state of infection, it is therefore the best tool for the quick survey of sources of infection

Bedson (1933) Lazarus and Meyer (1939) Hilleman (1943) and Labzoffsky (1946) have shown that the hyperimmune sera of guinea pigs rabbits, monkeys, and chickens *agglutinate* purified suspensions of elementary bodies in titers as high as 1 320 Agglutinins are, in fact, the only antibodies which besides protective properties, may be demonstrated in the sera of hyperimmune chickens and ducks Convalescent sera obtained from human beings contain agglutinins in diagnostically significant titers Studies by Meyer (1941) implicated phagocytic activity, possibly aided by humoral antibodies, in the immunity process Heat stable psittacosis antigens produce definite *allergic cutaneous reactions* in guinea pigs, and occasionally in man (Vilches et al, 1946) Free antigen fails to incite typical skin reactions in patients recovered from psittacosis or in carriers Antigens prepared from yolk sacs infected with meningopneumonitis or psittacosis virus produced skin reactions—erythema and induration—when injected intradermally into rabbits convalescent from respiratory meningopneumonitis infections (Morgan 1947)

PATHOLOGY

The changes found at autopsy are those of a general septicemia with inflammatory processes in the lungs Detailed pathologic data may be found in Haedke (1898) Leichtenstern (1899) Oberndorfer (1930), Hutchinson, Rowlands and Simpson (1930) Maclachlan Permar and Rogers (1930), Peterson et al (1930), Sturdee and Scott (1930), Bortz and Green (1930), Scholte (1930) Polayes and Lederer (1932), Lillie (1933), Foord (1934), Mansens (1934), Haagen and Kruekeberg (1937), Barros (1940), Binford and Hauser (1944), and Tanner et al (1945) This mass of literature emphasizes the following findings

Lungs—The consolidated areas are readily palpable and are sharply demarcated from normal lung tissues They appear as gray or gray-reddish,

sometimes as purplish or plum colored (*Binford and Hauser*) lesions without compensatory emphysema On section they are smooth moist glistening or of dry granular appearance The pleura may be glistening or exhibit petechiae and fine fresh fibrin deposits The trachea and bronchi may contain a small amount of serous mucoid fluid in the majority of cases they are empty and the mucosa is not swollen When the psittacotic process is complicated by secondary terminal bacterial invasion the bronchi are distended and filled with purulent exudate Tracheobronchial lymph nodes may be enlarged Microscopic examination invariably discloses that areas which grossly appeared to be completely consolidated consist of lobular changes not evenly distributed throughout the tissues Alveoli containing air or serum are dispersed through the consolidated portion of the lung substance Exudates in the alveoli are irregularly distributed and uneven in character The early lesions consist of outpourings of fluid into alveolar spaces and interstitial tissues accompanied by hemorrhages The septal capillaries are frequently plugged by hyaline thrombi In fully developed lesions the interstitial and interalveolar spaces contain abundant fibrin and a great number of lymphocytes macrophages and desquamated alveolar epithelial cells The composition of the alveolar exudate slight infiltration of the alveolar septa and little change in large bronchioles and bronchi give the anatomic type of pneumonia in psittacosis a very characteristic pattern It is doubtless not absolutely specific since in etiologically proved cases the wide dilatation of the peribronchial and perivascular lymphatics packed with mononuclear cells is quite similar to lesions seen in interstitial pneumonias associated with other viral agents However *Binford and Hauser* were able to note definite differences in the microscopic lesions produced in the lungs by psittacosis viral agents and those of Q fever or other virus pneumonias According to Polayes and Lederer (1932) the edematous swollen hemorrhagic larynx epiglottis and trachea show microscopically a mononuclear exudate with areas of extravasated blood All cells in the alveolar exudate and the lymph sinuses of the hilar lymph nodes show active phagocytosis and intracytoplasmic elementary bodies

In the **liver**, which is slightly enlarged with parenchymatous degeneration the characteristic microscopic lesions are paracentral or centrolobular focal necroses A proliferation and accumulation of macrophages and hyaline thrombi in the sinuses and interstitial tissues precede the development of necrosis Kupffer cells contain the elementary bodies The usual changes in structure of the **spleen** are those of an acute tumor having relatively small follicles and engorged sinuses filled with phagocytic cells Cloudy swelling and hypertrophy of the muscle are the principal changes in the **heart** Varying degrees of degenerative changes involve the parenchyma of the **kidneys** Hemorrhages and capillary thrombi have been observed in the adrenals in infections caused by the highly toxic Louisiana virus Congestion and edema of the **brain and spinal cord** are not infrequent Sprunt and Berry (1936) found no evidence of changes in the neurons but proliferative and degenerative changes in the capillary endothelium and hemorrhages which they attribute

to toxic factors secondary to the presence of pneumonia On the other hand Polayes and Lederer (1932) demonstrated proliferation of neuroglia and changes in the neurons they could find no evidence of demyelinization as claimed by Peterson et al (1930) and others

CLINICAL ASPECTS

Clinically recognized psittacosis in man is a severe illness with a high mortality in the older age groups of both sexes Mild ambulatory cases and latent infections occur in fact persons exposed to the same infective agent may suffer from the disease in completely different degrees of severity The duration of the actual disease is usually 2 to 3 weeks Convalescence is nearly always protracted and tedious

SYMPTOMATOLOGY

From the many clinical descriptions published since 1879 (Hegler Adams Sturdee and Scott Hutchinson Rowlands and Simpson Peterson Spalding and Wildman Thomson and Hillier 1930 Grassi et al and Parros 1940 Garcia 1940 Lozzola et al Loizaga and Averbach) the strikingly uniform manifestations confused with influenza atypical pneumonia and typhoid fever repeat themselves with remarkable regularity A characteristic of the disease is the disparity between the extent and severity of findings discovered upon physical examination and the superficial appearance of well being which the patients exhibit only to be followed abruptly by a state of collapse

The incubation period, when determined with certainty varies from 7 to 14 days (average 10 days) after exposure 2 to 3 weeks may elapse between the acquisition of birds and onset of the first case In 3 cases in which single exposures occurred for a few hours the incubations were 7 8 and 9 days respectively An interval of 8 13 and 30 days respectively elapsed between the onset of illness and the discharge of three nurses from care of psittacosis patients When the disease is transmitted from one human case to another it may have an incubation time as short as 4 to 6 days (Hegler 1930 Sturdee and Scott 1930 Loizaga and Averbach 1945) An exceptionally long incubation of 82 days (Armstrong et al 1930) may possibly be explained as a relapse of latent infection provoked by another intercurrent infection

The onset may be sudden with chilly sensations fever anorexia sore throat general malaise and severe headache or the first symptoms may often be very vague and the beginning of the illness gradual and insidious **The fever** in many respects similar to that of typhoid fever is usually 100° to 102° F with a gradual rise of the stepladder variety During the second week in severe cases the temperature maintains itself at a high level with slight morning remissions even in fatal cases or may fall to normal about the seventh or eighth day in mild cases Termination by crisis is rare and during convalescence the temperature may be subnormal **The pulse** is apt to be slow in relation to temperature Nose bleed occurs in 25 per cent of the cases The

headache may be occipital nuchal or frontal it is intense intractable and not relieved by the usual analgesics

Except in mild cases **pulmonary involvement** manifest by its objective signs *is an essential* feature of human psittacosis A slight irritating dry cough during the first few days may persist or increase in intensity to painful paroxysms, cough despite extensive lung signs may be insignificant or absent throughout the illness The sputum is always scanty or entirely absent it is at first mucoid but later may become mucopurulent In rare instances it is tinged with blood usually when copious secondary infection is an accompaniment Abnormal signs about the lungs are often scanty The earliest demonstrable changes may be confined to an area of dullness on percussion at the bases of the lungs Crepitations may be heard as early as the fifth *day Usually the real* extent of pneumonitis is not evident until roentgenologic examination is made The wedge shaped appearance of the early pulmonary process is frequently of diagnostic significance as well as the scattered *patchy areas of consolidation over one or both lungs which give psittacosis* the picture of a migrating pneumonia Pleural reaction is generally slight or absent Physical signs begin to disappear by the beginning of the third week but x ray examinations disclose a slow but ultimately complete resolution Despite extensive involvement of the lungs the rate and depth of respirations are not increased except in fatal cases in which a rate as high as 60 has been reached

The relative slowness of the **pulse** is a characteristic feature throughout the course of the illness In nearly all fatal cases the pulse becomes rapid and weak cyanosis and low blood pressure may be marked, collapse at some time during the illness is common Thrombophlebitis has been known to occur and may cause relapses and death due to pulmonary thrombosis Insomnia restlessness followed by drowsiness disorientation apathy mental depression and even delirium may occur in *all except mild cases Photophobia* accompanies the headache

The **gastrointestinal tract** is involved in most cases Nausea and vomiting are common early *symptoms The tongue is furred Either* constipation or diarrhea may be present The spleen is palpable in very few cases Albuminuria of varying degrees is not infrequent and *transient glycosuria* has been reported Skin rashes or rose spots have been noted by Gastou (1892) Horder and Gow (1930)

The **blood picture** in psittacosis is not markedly altered The leucocyte count is usually normal or subnormal definite leucopenia is found in only 25 per cent of the patients Leucocytosis occurs late in the acute phase or in early convalescence No significant abnormalities are noted in the hemoglobin percentage or in the bleeding and coagulation times

Relapses particularly in cases inadequately treated with serum or penicillin are by no means uncommon With the aid of newer diagnostic procedures and in the course of epidemiologic surveys mild and inapparent infections are being recognized with increasing frequency *The symptomatology*

to toxic factors secondary to the presence of pneumonia On the other hand Polayes and Lederer (1932) demonstrated proliferation of neuroglia and changes in the neurons they could find no evidence of demyelinization as claimed by Peterson et al (1930) and others

sons has been used In general doses of from 50 to 200 c c have been administered intramuscularly or intravenously It is difficult to judge *objectively* the value of the treatment since neutralizing antibodies are rarely present in the sera and in animal experiments human convalescent serum exerted no curative effect In the early experiments by Rudd and Burnet (1941) and unpublished observations of Eddie and Meyer *there is no experimental proof that any of the sulfonamide compounds is of value on two strains of the psittacosis virus* More recently Meiklejohn et al (1946) have shown that sulfadiazine is effective against two classical strains which may in part explain the clinical cure reported by Hinshaw (1940) Significant and in harmony with the biology of the viral agent are the observations that mice which survived *the infection became carriers after therapy was discontinued*

In view of the *greater effectiveness of penicillin* on all the strains thus far tested there is no need to resort to sulfonamide therapy Heilman and Herrell (1944) Bedson and May (1945) Meiklejohn et al and Wiseman et al (1946) produced evidence that experimental psittacosis in the mouse responds to treatment *with penicillin* The workers at the Hooper Foundation (Meyer and Eddie 1947) treated experimentally infected mice and ricebirds Therapeutic results were convincing provided treatment was instituted early in the course of the infection and the antibiotic was used in large doses Ricebirds were apt to die from relapses 22 to 27 days after intensive treatment with 6 000 000 units over a period of 17 days had been discontinued *Successful* treatment of human psittacosis has been reported by Turgasen (1944) Flippen Gaydosh and Fittipoldi (1945) and by Meyer and Eddie (1947) Observations suggest that the antibiotic acts on the extracellular phase of the viral agent when it is not actually multiplying Whenever the immunity mechanism is sluggish or impaired by toxin action *penicillin treatment must be prolonged* until the antibodies of the host are capable of taking over the bacteriostatic and bacteriolytic effect of the antibiotic The dynamic action of penicillin on psittacosis specifies a high dose level (40 000 to 100 000 units every 4 hours) in rapid succession early in the course of the infection in order to reduce the number of viral elements and to permit the normal body *defense* mechanism to dispose of the few stragglers Adherence to these principles *will greatly reduce* the unduly high human case fatality rate from psittacosis and prevent the development of virus carriers

LABORATORY DIAGNOSIS

The laboratory diagnosis of psittacosis requires considerable time and the ultimate isolation of the specific virus in the sputum or blood is *from* the patient s standpoint largely an academic matter Therefore recourse is *made to the indirect method of diagnosis* which consists of the demonstration of specific antibodies

Isolation of the Virus During Acute and Convalescent Phase of Psittacosis and at Autopsy—During the acute and convalescent phase of suspected cases of psittacosis every effort should be made to isolate the virus by inoculation *of mice with specimens of citrated* human blood or sputum when they are ob

of mild cases has been described by Sturdee and Scott (1930) The patient is feverish with headache and general pains in the limbs and the attack may last for only a few days

DIFFERENTIAL DIAGNOSIS

Definite as is the clinical entity of psittacosis in man nevertheless certain diagnosis in any one case and in any one stage of such a case may offer great difficulty A typhoid like illness with pulmonary involvement and negative Widal test is very suggestive of psittacosis A clean cut separation of the patients from those who have pneumonitis due to other causes is quite difficult (Reiman 1947) Furthermore the response of the lung tissue to psittacosis infection resembles that described for other viruses Clinically roentgenologically and pathologically the psittacotic pneumonias resemble the severest forms of commonly occurring viral pneumonias A history of association with birds suggests a diagnosis of psittacosis but recently cases of influenza or so called atypical pneumonia with no definite history of avian exposure have been ultimately diagnosed as psittacosis Moreover recent facts definitely contradict the observation that a person to person type of spread prevails in influenza only

PROGNOSIS

The prognosis of psittacosis is difficult As long as the pulse remains below 100 the ultimate outcome is invariably good Until recently the *case fatality rate* of reported cases has been uniformly high (approximately 20 per cent) in the United States Germany and Argentina In the 167 cases reported by Armstrong it was 24 per cent in 301 other cases it was 17 per cent In a house epidemic due to parakeets observed by Meyer Eddie and Stevens (1935) all four victims died According to Fortner and Pfaffenberg the rate in Germany for 106 cases was 18 per cent in 1933 1934 then 20 per cent but it rose to 36 per cent in a group of 25 cases in 1937 1938 (Haagen and Mauer) The 186 cases described in the *Rev med Argentina* had a fatality rate of 39 or 20 per cent however in the outbreak described by Loizaga and Averbach the fatality in 28 cases was 13 or 46 per cent With the recognition of mild and ambulatory infections the case fatality rate in a series of 228 cases studied between 1940 and 1946 dropped to 21 or 9 3 per cent (Meyer and Eddie 1947) As a rule the age groups 40 to 60 are particularly liable to fatal infections With the introduction of penicillin as a therapeutic agent it is anticipated that the fatality rate will be further reduced

TREATMENT

Symptomatic treatment and careful nursing should be conducted along lines similar to recognized procedures used in pneumonia Isolation in a quiet environment is imperative in order to reduce the risk of person to person transmission Since 1930 the *serum of convalescent* and even of normal per

tainable The diagnosis of human psittacosis is usually made in retrospect since not infrequently the virus is present in small quantities and repeated animal passage may be required for its demonstration (see Rivers and Berry 1935 Bedson 1936 Systematic inoculation of lung and splenic tissues from autopsies with lesions of pneumonitis has with increasing frequency led to the isolation of the psittacosis virus In a series of 228 cases of clinically and serologically proved psittacosis the nature of the infection was established in 52 or 22 per cent (Meyer and Eddie 1947)

Complement Fixation Test—Demonstration of complement fixing antibodies is being used with increasing success to demonstrate that a given acute illness is caused by a member of the psittacosis lymphogranuloma group Although at present it is impossible to differentiate sharply between human psittacosis and lymphogranuloma venereum serologic tests are frequently the only means of making a rapid diagnosis (see Meyer 1942 Smadel et al 1943)

The ubiquity of elementary body viral agents capable of inciting antibodies in man places restrictions on the diagnostic value of the complement fixation test In persons not previously exposed to viruses of the psittacosis lymphogranuloma group complement fixing antibodies may appear in the sera as early as within a week (fourth to eighth day) after the onset of symptoms If the titer rises within the next 4 or 5 days a tentative diagnosis of psittacosis may be rendered and specific treatment instituted Additional serum specimens should be examined and the rise in titer noted A serum with a titer of 1 16 or greater when obtained from a patient with clinical manifestations suggestive of psittacosis may be considered positive as a rule a fourfold or more increase in titer is observed during convalescence Precautions are necessary in the interpretation of the tests

Patients with a positive Wassermann reaction may react strongly with the psittacosis antigen when they are simultaneously infected in a latent stage with the virus of lymphogranuloma (Rake and Jones 1944) The sera of patients with acute infections may occasionally yield significantly high complement fixation titers which fade during convalescence in contrast to the psittacosis infections in which the titer rises during convalescence and usually persists for many months even years These fleeting reactions are probably anamnestic and may result from the reappearance of antibodies indicative of a previous unrecognized latent infection Individuals constantly exposed to psittacosis agents such as aviary owners pet shop employees pigeon breeders etc as a rule show complement fixing antibodies in their sera in titers varying from 1 8 to 1 32++++ (see Meyer 1942) Cold agglutination of erythrocytes and agglutinins for streptococcus MG do not appear in significant titer in psittacosis (Finland 1945)

PREVENTION

Prevention of psittacosis is difficult because the nature of the disease is recognized only when it appears in epidemic form Rigorous isolation should be applied to all severe cases during the febrile and acute clinical stages of the disease Patients with coughs should not be examined or treated without

WESTERN TYPE OF EQUINE ENCEPHALOMYELITIS

Eklund and Blumstein (1938) reported 6 cases of encephalitis among farmers in Minnesota in 1937, all of whom had been in contact with horses sick with equine encephalomyelitis. Two of the men died after an illness of four to five days, and the third after an illness of weeks. It was found that the serum of 1 of the surviving 3 neutralized the Western strain of equine encephalomyelitis virus (in January, 1938). Howitt (1938), during the California outbreak, isolated a "Western" strain from the brain of a child, and in the next year from the blood of a man showing symptoms of encephalitis. Fothergill, Holden, and Wyckoff (1939) isolated the virus from the spinal fluid. Wheeler (1941) reported that 50 per cent of patients with encephalitis in Kansas showed antibodies for this "Western" type.

The Western variety of equine encephalomyelitis has been recognized as one of the most prevalent forms of encephalitis. In the summer of 1941 alone, 1,700 cases were recorded in Minnesota and North Dakota. Howitt (1942) examined 498 human sera from cases with diseases produced by neurotropic viruses and found that 213 (42.3 per cent) neutralized the Western virus. Leake (1941) reported on a large epidemic which occurred in North Dakota, recording 96 deaths from a total of 1,080 patients, an incidence of 167 per 100,000 and a mortality rate of 8.9 per cent. Wheeler (1941), Casals, Curnen, and Thomas (1943), and Lennette and Koprowsky (1943) reported laboratory infections and emphasized the high contagiosity.

LATIN AMERICAN STRAINS OF EQUINE ENCEPHALOMYELITIS

Rosenbusch (1935) isolated in Argentina a horse virus similar to the Western type. Tabusso (1935) and Schmidt (1936) found the same type in Peru and Chile, respectively. Kubes and Rios (1939) found in Venezuela a new encephalomyelitis virus that was reported again by Soriano Lleras and Figueroa (1942) from Colombia, and by Kubes (1943a) from Trinidad.

Shahan and Giltner (1945) reported that in 1944 an epizootic of equine encephalomyelitis occurred in Cuba; five strains submitted for examination were of the Eastern type. A vaccine was prepared from one of the Cuban strains. This protected equally well against the homologous strain, one of the other Cuban strains, and a representative Eastern virus from the United States.

Early in 1945, a sample of guinea pig brain, from infection with a supposed equine encephalomyelitis virus, was received from Ecuador. Guinea pigs immune to Eastern and Western virus succumbed to intracerebral inoculation with this virus. All guinea pigs immunized with Venezuelan type vaccine withstood intracerebral challenge with approximately 100 M.L.D. of the Ecuadorian virus, which was thus diagnosed as the Venezuelan type.

The vaccine prepared with the Venezuelan strain conferred complete protection against the homologous virus and the virus isolated in Trinidad (Kubes, 1943).

In 1913 and 1915 the Brazilian literature recorded clinical observations on equine encephalomyelitis. In March, 1937, in Tatuhuy, state of São Paulo, an epizootic was studied by Carneiro (1937). The virus isolated at that time seemed to be similar to the Argentina (Western) virus, but in further trials made by Carneiro and Cunha (1943) and Carneiro (1944) it was not possible to detect immunologic relationship between the Brazilian, the Argentinian, a strain of Western type from California, and the Venezuelan type viruses. The immunologic relationship to the Eastern type virus is much closer, though incomplete. To these authors it seemed that the Brazilian strain should be classified as a variety of the Eastern type.

According to Valdés et al. (1943), there was an epidemic of meningoencephalomyelitis in Córdoba, Argentina, during the autumn and summer of 1940 and 1941. Some scattered

CHAPTER 21

ENCEPHALITIS AND ALLIED DISEASES

Luis Vargas

EQUINE ENCEPHALOMYELITIS

The first published reference to equine encephalomyelitis is attributed to Large of the New York City Veterinary College, who in 1867 described the disease among horses on Long Island. The next paper was published by Williams (18[illegible]8) who described an outbreak in the Snake River Valley of Idaho. Buckley and MacCallum (1901) reported on an outbreak of equine encephalomyelitis in Maryland. Meyer, Haring and Howitt (1931) reported that in their investigation of a highly fatal outbreak among horses and mules in the San Joaquin Valley of California they isolated a filtrable virus responsible for the epizootic disease then prevalent. As the [illegible] was found to produce inflammation of both the brain and spinal cord they designated it [illegible] encephalomyelitis. This strain later was designated as the Western strain of equine encephalomyelitis. The first case appeared in July and continued to occur in large numbers until the advent of cool weather in October and November, when the disease disappeared. In the San Joaquin Valley outbreak in 1930 about one horse in ten was involved; from approximately 5[illegible] per cent of the cases terminated fatally.

EASTERN TYPE OF EQUINE ENCEPHALOMYELITIS

According to Randall (194[illegible]) in 1933 the disease appeared in horses along the Atlantic Seaboard (Giltner and Shahan, 1933) and Ten Broeck and Merrill (1933) reported isolation of an Eastern strain of equine encephalomyelitis virus which, though similar to the Western type, differed from it immunologically.

Epizootics of the Western variety among horses have been characterized by a high attack rate, a low fatality rate and a subacute form of the disease. Epizootics of the Eastern variety are characterized by a low attack rate, a high fatality rate and a more acute and fulminating type of disease. The areas of Eastern and Western equine encephalomyelitis are divided by the Appalachian range of mountains. In Alabama, which lies directly at the southern end of this mountain range, both forms of the malady are known to have occurred. In the spring of 1941 Randall and Eichhorn (1941) isolated the Eastern strain from a suspected horse from Brownsville, Texas. Téllez Girón and Valdez Ornelas (1941) identified the same strain in an outbreak in the state of Tamaulipas, Mexico.

Meyer (193[illegible]) suggested the possibility of human infection. He reported briefly 3 cases of encephalitis [illegible] in men closely associated with horses having equine encephalomyelitis. He was unable to isolate the virus from a fatal case or to demonstrate neutralization of the virus of equine encephalomyelitis by blood serum obtained during convalescence from a nonfatal case. He presented these cases with the suggestion that in the future the central nervous systems of patients who have died of typical human encephalitis be investigated for the presence of the virus of equine encephalomyelitis. Fothergill, Dingle, Farber and Connerly (1938) and Webster and Wright (193[illegible]) isolated in Massachusetts the Eastern type virus from human brains coincident with an epizootic in horses. It was the first time that equine encephalomyelitis had been demonstrated in infected species other than horses and mules.

The virus of Japanese encephalitis has been isolated from *Culex pipiens* var *pallens* and *Culex tritaeniorhynchus* in epidemic areas by both Russian and Japanese workers, and Culex, *Aedes togoi*, *Aedes albopictus*, and *Aedes japonicus* have been shown to be capable of transmitting the disease to mice or monkeys in the laboratory. Mitamura et al (1937, 1940) reported that mosquitoes bred in the laboratory from larvae or eggs collected in an epidemic area were occasionally infected. It has been reported that a virus of encephalomyelitis infection of mice somewhat similar to Theiler's virus is encountered in laboratory mouse colonies in the East, which, clinically, in animal susceptibility range, and even serologically, cannot be readily differentiated from Japanese B virus encephalitis. To prevent the establishment of this virus from accidental introduction we must control more species than Anopheles and *A aegypti* near air and seaports. The genus Culex and certain other genera can no longer be considered mere pests.

Mitamura et al (1940) reported the transmission of St Louis virus by *Culex pipiens* var *pallens*, *Culex tritaeniorhynchus* and *Armigeres obturans*. The Western type was transmitted by Culex.

Hammon and Reeves (1945) report that more detailed laboratory tests on inoculated chickens have shown that a very high dilution of St Louis virus, if inoculated subcutaneously into a chicken, gives rise regularly to a virus concentration in the blood to a titer higher than in the inoculum, for a period of 2 or 3 days, occasionally for as long as 4 days. No mammal thus far tested has proved to be as good a potential source of mosquito infection. However, despite this apparently satisfactory and well established concept of the epidemiology of this disease, mosquito fowl mosquito and occasionally a biologically aberrant infection mosquito to man or horse, the cycle is still incomplete. Chickens and other birds tested have shown no evidence of ability to serve as chronic or latent carriers of the virus. Hibernating *C tarsalis* and *C pipiens* collected during the winter in Washington and California have not been found infected so far, although 5,429 have been tested. These results do not support the early hypothesis of winter "carryover," presented by Hammon et al (1941, 1942) based on the fact that many Culex hibernate as adults. In addition, they tested the eggs and progeny of infected *C tarsalis* and *C pipiens* and found no evidence of transovarian passage of the virus. Therefore, the true reservoir or the whereabouts of the virus during the winter and during the seasons when there is no apparent infection is unknown.

Hammon and Reeves (1945) state that one strain has just been isolated from *Aedes dorsalis* (Meigen) caught in Kern County, California. This is the first isolation of St Louis virus from any source in California, although serologic evidence of its presence had been repeatedly obtained. It is also the first isolation of St Louis virus from an Aedes mosquito.

In the West, most of the cases have occurred among adult male farm workers in contrast to the Eastern type infection which has had the highest incidence in children. In 28 cases studied in the Yakima Valley, Washington, by Hammon et al (1945), the mean age was 36, as compared with 46 for 1940 and 25 for 1941. They recorded 4 cases in children less than 1 year old, males greatly predominating only in the adult and teen age working group. By using five New Jersey type light traps, they showed that the activity of *C tarsalis* correlated well with the epidemic curve.

Hammon and Reeves (1942, 1943, 1943a) have demonstrated that *C tarsalis* is an efficient vector of both Western equine and St Louis viruses. It feeds predominantly on fowl and occasionally on mammals. It becomes readily infected by feeding on fowls at a time when virus is present in the blood, and mosquitoes infected become, in turn, infective by their bite after a suitable extrinsic incubation time at proper temperatures. It thus appears that this species is an important vector of both Western equine and St Louis viruses.

Hammon and Reeves (1945) found *C pipiens* infected with St Louis and Western equine viruses. This species is also used in the laboratory as a vector of St Louis virus and thus can be considered a natural vector. However, in all laboratory tests, this species has lost every detectable trace of Western equine virus in 24 hours. It would appear that the recovery of Western equine virus from a mosquito of this species in nature is an indication that the

cases had previously been observed, but this was the first epidemic of encephalitis to be recognized in Argentina The author observed 80 cases in the University Hospital, with a higher incidence in children Of 67 seriously ill patients, 40 per cent died, and 16 per cent presented serious aftereffects such as hydrocephalus, epilepsy, and mental disturbances Of the entire group, only 44 per cent recovered without sequelae Neutralization tests with convalescent sera were negative with the Japanese B and St Louis, as well as Eastern and Western equine encephalomyelitis viruses.

The infection was transmitted to white mice by inoculation of an emulsion of brain material, it was possible, too, to convey the infection from mice to mice The epidemic coincided with an epizootic in horses and was followed by one in birds

In Cordoba Argentina, cases of infantile encephalitis have been confirmed several times since late in 1940 Valdés et al (1943) observed cases in children born of apparently healthy mothers These authors described 8 cases at ages ranging from 5 days to 9 months, all were studied clinically and pathologically and presented the first signs without any exception a few hours or days after birth

Soriano Lleras (1943) pointed out that Ordonez in 1943 reported that in Bogotá and Tenjo he had observed 7 human cases of encephalomyelitis He added that the disease was described for the first time in Colombia by Franco in 1923 Guerrero, in 1927, collected 6 more cases, one in La Dorada and five in Bogotá Ordonez in 1940 observed the disease in Bogotá Bucaramanga La Dorada and Tenjo, but the etiologic agent was not clear It is believed that there was a severe outbreak in that year Early in 1941, in La Sabana, and especially in Bogotá equine encephalomyelitis appeared in epidemic form, Soriano Lleras (1943) established that the agent was the Venezuela type virus The rarity of human cases contrasts with the frequency with which equine encephalomyelitis appears this having been studied by Tavares in Tolima more than twenty years ago later, epizootic outbreaks occurred in El Cauca, Atlantico, Valle, Tolima Bolivar, Huila Magdalena, La Guajira, Arauca, Cundinamarca, and Antioquia

TRANSMISSION

It has been observed that the disease appears in early summer, reaching its peak late in August or September and disappearing with the coming of killing frosts Infection follows natural water courses and irrigation systems, Its greatest prevalence is in rural areas among horses kept in the pastures at night Meyer et al (1931) had expressed the belief that the virus is transmitted by an insect vector

Kelser (1933) proved that the mosquito *Aedes aegypti* is capable of transmitting the virus of equine encephalomyelitis from guinea pig to guinea pig and from guinea pig to horses It was further shown that the transmission was not mechanical but occurred after multiplication of the virus within the mosquito and that once infected the insect was capable of transmitting the disease for most, if not all of its ordinary life Simmons Reynolds and Cornell (1934) proved transmission of the disease by *Aedes albopictus* Merrill, Lacaillade, and Ten Broeck (1934) succeeded in transmitting both Eastern and Western strains through *Aedes sollicitans*, the New Jersey salt marsh mosquito, and also *Aedes cantator* Madsen and Knowlton (1935) added *Aedes nigromaculis* and *Aedes dorsalis* to the list of transmitters, and Ten Broeck and Merrill (1935) and Kelser (1937) added *Aedes vexans*, Kelser (1938) added *Aedes taeniorhynchus*, Davis (1940) added *Aedes triseriatus* to this group of experimentally infected mosquitoes Hammon et al (1941) reported that *Culex tarsalis* was found to be harboring the virus in nature They found that the same species of mosquito harbors the virus of St Louis encephalitis Hammon and Reeves (1943) demonstrated transmission by *Aedes lateralis* (Meigen) Syverton and Berry (1936) showed that the Rocky Mountain spotted fever tick, *Dermacentor andersoni*, is capable of transmitting the disease experimentally from guinea pigs to ground squirrels and further suggested that the gopher, *Citellus richardsoni*, may be the natural host of the virus because of its susceptibility

first isolated appeared to be of low virulence but the virulence was built up rapidly by serial passage. The virus also killed consistently following intranasal instillation and foot pad inoculation.

IDENTIFICATION AND PROPERTIES

The virus of equine encephalomyelitis is estimated to be from 20 to 30 mμ in size. It may be preserved in 50 per cent glycerin under refrigerated conditions for some time. It apparently loses its virulence quite readily in a dried condition. It is easily destroyed by heat and by chemical preparations commonly used as disinfectants.

Calla (1944, 1945) investigated the in vitro effect of different drugs on the Venezuelan equine encephalomyelitis virus. No antibiotic known to date (1949) is effective.

SYMPTOMATOLOGY

Eklund (1942) and Leemster (1938) described the disease in human beings as follows: The clinical picture in human encephalitis of the Western type closely resembles the St. Louis disease. There is usually an abrupt onset with severe headache and high fever, together with chills, chilly sensations, nausea or vomiting, pain in the neck, the back, the abdomen, or in the extremities. In young children the onset is sudden, with high fever and convulsions. A day or two after the onset drowsiness appears, the temperature continues to be elevated. The patient becomes mentally retarded and when not disturbed drops off to sleep. Shortly thereafter tremors about the mouth and hands may appear. Delirium and disorientation take place in some cases; in others drowsiness progresses to coma. Rigidity of the neck muscles is the most frequent finding, but lack of abdominal reflexes and tremors of the lips, tongue and hands are common. Less frequent are positive Kernig and Babinski signs, abnormal tendon reflexes, difficulty in speech and swallowing are rather uncommon except in children. Mental retardation and paralysis sometimes occur. The temperature is high for about five days, then it drops rapidly. About two days after the temperature declines the symptoms improve and in ten to fourteen days the patient is well on the road to recovery.

In fatal cases the fever continues high, drowsiness progresses to coma, and death usually follows in 5 to 7 days. The mortality from the Western type appears to be about 10 per cent, although 7 to 20 per cent have been reported.

In the Eastern infection, onset is more abrupt, pointing to an early and severe invasion of and injury to the central nervous system; high fever, vomiting, and appearance of drowsiness or coma all becoming manifest in 24 to 48 hours. The cerebrospinal fluid is under increased pressure, of hazy to ground glass appearance, with cell counts varying from 200 to 2,000 per cubic millimeter, from 60 to 90 per cent of the cells are polymorphonuclear leucocytes. There is a high fatality rate (75 per cent), a predilection for children and marked sequelae in the survivor, such as paralysis and mental changes.

According to Adamson and Dubo (1942), a patient affected by equine encephalitis Western type has the aspect of and acts like a person alcoholically

specimen had recently engorged on an infected reservoir and that the virus probably would have disappeared within a few more hours.

Culiseta inornata is capable of acting as a vector in the laboratory and if present in large numbers might serve as a vector of importance. *Anopheles freeborni* has been demonstrated to lose all detectable virus within 4 hours.

The Western type of equine encephalomyelitis virus was isolated by Sulkin (1945) from chicken mites *Dermanyssus gallinae* (de Geer) in nature during an outbreak in which there were at least 3 cases of infection in man. Smith, Blattner and Heys (194) reported the isolation of the St. Louis virus on three different occasions from *D. gallinae* and demonstrated the infection in the progeny.

It is believed by Gallyard (1944) that in Trinidad the principal vector may be *Taeniorhynchus titillans* but other species cannot be excluded. The virus has been isolated from mosquitoes captured in the field and the vaccine elaborated with the Venezuelan virus has fully protected experimental animals against it. A fatal human case is reported in a sailor about 40 kilometers distant from the animal outbreak and is considered as the first human case of equine encephalomyelitis virus Venezuelan type. *T. titillans* is a common mosquito ranging from the southeastern states of the United States to South America. This author was able to demonstrate for the first time a mosquito to infect on from a large mammal with any of the equine viruses. This is therefore another arthropod-borne virus encephalitis affecting man with large mammals including horses and man among the hosts from which mosquitoes may become infected. Similar in this respect is the Japanese B virus.

In some experiments *Stomoxys calcitrans*, *Tabanus punctifer* and *Haematobia serrata* were not proved to be capable of being vectors of equine encephalomyelitis.

Remlinger and Bailly (1936, 1936a) reported a large number of birds to be susceptible to the Argentine virus. These included the greyleg goose (*Anser cinereus*), the black (*Circus rufus*), the European blackbird (*Turdus merula*), the tawny vulture (*Vultur fulvus*), the white stork (*Ciconia ciconia*) and the mallard duck (*Anas boschas*). The Argentine virus is immunologically identical with the Western virus.

Nevertheless the reservoir of the encephalomyelitis virus is unknown. The horse does not seem to be a suitable reservoir according to Randall (194?) since the virus can be isolated from its blood stream only during the early stages of the disease and a chronic carrier state has not been established. Pheasants, pigeons and prairie chickens have been found infected under normal conditions. Hammon et al. (1941), working in the Yakima Valley, found the blood serum of many mammals and birds from the region to show neutralizing antibodies to the virus. The avian species included the chicken, goose, dove, pigeon, turkey, flicker, killdeer, pheasant and quail; the mammals included the cow, dog, goat, horse, pig, sheep, field mouse and weasel. This indicates the wide host range of the virus. As mosquitoes readily feed on mammals and birds this further stresses the importance as vectors of the disease.

Inoculation into a wide variety of vertebrates by dermal routes has not afforded any results suggesting a true reservoir state but Blattner and Heys (1944) found that *Dermacentor variabilis* (Say) is capable of transmitting the infection and that transovarian infection occurs, thus suggesting a potential reservoir. Hammon and Reeves (1945) note however that no naturally infected ticks have been found and there is little to suggest that the dog might serve as a link to infect ticks. Moreover *D. variabilis* is unlikely at any stage in its development to infest fowl. These authors found a heavy chicken tick infection of *Argas persicus* (Oken) in the San Joaquin Valley. However none was found infected among 9,9?8 tested during 1943 and 1944 but in the laboratory experimental infection has persisted at least ...

Syverton and Berry (1936) were able to infect *D. andersoni* and they demonstrated transovarian infection.

Kitselman and Grundmann (1940) isolated the virus fatal to guinea pigs from *Triatoma sanguisuga* Leconte collected from a pasture near Carrison, Kansas. The virus when

from the brain at autopsy. It has rarely been isolated from the blood or spinal fluid. Usually the diagnosis is made by the neutralization test in which a series of tenfold dilutions of the virus are made. Virus suspensions diluted 1:1 000, 1:10 000 and 1:100 000 are mixed with equal amounts of the patient's serum, and groups of mice are inoculated intracerebrally. If the patient has had the disease, the mice will be protected; serum may have protective power as early as one week after onset of the disease. The time when the serum has its maximum protective power is not known, but when taken at the end of the second or third week will probably in most cases show protection. Protective antibodies have been demonstrated in the sera of patients two years after recovery from the disease, and it is possible that they may persist longer. Sera of patients with no history of encephalitis seldom show protection, so that a positive neutralization test, together with the clinical findings of encephalitis, justifies a diagnosis of encephalitis of the equine type. It is preferable, if possible, to secure blood serum early and demonstrate that antibodies are not present early in the disease but are developed during the illness or convalescence.

As Shahan and Giltner (1945) state, infection by equine encephalomyelitis virus is almost invariably followed, in the event of recovery, by the formation of virus-neutralizing antibodies in the blood serum. In some few cases these may endure for a comparatively short time but they usually persist for months. The antibodies develop after inapparent or occult infections and after vaccinations with formalin-inactivated virus such as is utilized in the present-day chicken embryo vaccine.

Noran and Baker (1945) state that the lesions in Western equine encephalitis may be progressive, resulting in a chronic form of this disease, especially in infants and children. In one case they found that cysts had replaced both frontal lobes and were separated from one another by glial tissue. The rest of the brain represented widespread parenchymal changes consisting of diffuse and focal areas of demyelinization. The vascular involvement varied from collars of perivascular infiltrations to the narrowing and occlusion of the vessels by an endothelial proliferation. Vascular calcification was prominent. Apparently the vascular alterations indicate that the parenchymatous lesions are secondary to cerebral ischemia. The outstanding pathologic changes in the blood vessels suggest a vascular spread of the equine virus.

Kubes (1943) systematically studied the immunologic relations between the Colombian and Venezuelan viruses. The results obtained suggest the immunologic identity of both viruses. Nevertheless the antigenic potency of the vaccine elaborated with the Venezuelan virus is higher than with the other.

Havens et al. (1943) found a definite cross reaction in the complement fixation test between Eastern equine encephalomyelitis and Western encephalomyelitis viruses. On the other hand the conclusions reached by Casals (1945) were that by complement fixation test with guinea pig hyper

intoxicated in the first degree showing a red face sweat, tumefaction with mask expression and redness of the eyes and nose Speech is difficult, there are tremors of the tongue lips and hands Notwithstanding the intense cephalalgia somnolence and mental confusion the patient seems to be only slightly worried about his condition and probably after recovery will not recall any details of his illness In addition the patient shows absence of abdominal reflexes but the Babinski sign is positive there is nystagmus and the cerebrospinal fluid shows monocytes

The most convincing proof of the disease is a positive complement fixation reaction* or the neutralization test In localities in which equine encephalomyelitis has been observed an unknown proportion of the population perhaps may show positive blood reactions The serum may be negative during the first weeks and even later The test must be repeated in all suspicious cases

Clinically it is very difficult to differentiate the disease from poliomyelitis cases with slight encephalitis may resemble serious poliomyelitis cases In this latter perhaps one may observe cephalalgia somnolence sweating mental disturbances and abnormal reflexes characteristic of encephalitis Rigidity of the neck muscles and paralysis indicate poliomyelitis nystagmus tremors and monocytes in the cerebrospinal fluid all point to encephalitis The acute symptoms of poliomyelitis disappear within 4 to 5 days while those of encephalitis perhaps may last one week

The pathology of the disease in man is reported as similar to that described for animals. It is stated that in man the general type of pathology in lethargic encephalitis St Louis encephalitis and encephalomyelitis is practically the same the differences consisting chiefly in the degree and extent of involvement

Randall (1942) sounds a note of caution about brain material from fatal suspected cases submitted to laboratories for virus isolation shortly after death certain chemical changes take place with formation of lactic acid, that readily destroy the virus Therefore in suspected cases that end in death remove the brain promptly and place selected portions of it in sterile 50 per cent buffered glycerin The virus will remain viable for many days The brain material in a dilution of 1 100 should be injected intracerebrally into three groups of guinea pigs One group should be previously immunized against the Western type the second group against the Eastern type and the third group not immunized If equine encephalomyelitis virus is present all of the guinea pigs except those immunized against the specific type should die in 3 to 5 days In a typical case in man a diagnosis of encephalitis should not be difficult but it is impossible to state whether it is the St Louis or equine type It is often difficult to differentiate this disease from abortive poliomyelitis or tuberculous meningitis and when there are no neurologic findings from the common infectious diseases such as undulant fever An etiologic diagnosis can often be made The virus itself is most often isolated

*Editor's note (O F) Lederle Laboratories Inc and the Markham Laboratories, Chicago Ill produce reliable antigens for such tests

vessels become compressed or even obliterated The usual infiltrative elements are lymphocytes, plasma cells are rare and appear late in the infection other cells are the same as in the pia—polyblasts fibroblasts and rod cells They are all confined to the adventitial spaces of Virchow Robin In some cases the infiltrations are so dense that they overflow these spaces and invade the surrounding parenchyma The perivascular infiltrations are especially prominent in the substantia nigra around the Sylvian aqueduct, and in the optic thalamus Hemorrhage and softening are as a rule absent and polymorpho nuclear cells may be present in very acute or peracute cases Small scattered hemorrhagic foci occasionally may be seen but they are not associated with reactive glial phenomena and thus may be considered agonal

Poliomyelitis may resemble epidemic encephalitis The main differential feature however as pointed out by Hassin (1933) is in the parenchymatous changes which are present in the anterior horn cells in poliomyelitis Here within a few days or even hours the ganglion cells may become destroyed as evidenced clinically by sudden paralysis and early degenerative muscular atrophy In epidemic encephalitis the majority of the ganglion cells are un affected or exhibit only a slight cloudy swelling mild chromatolysis and occa sional neurophagia Mild as the inflammatory phenomena in the spinal cord are their presence in encephalitis justifies the designation of the latter as a disseminated encephalomyelitis

Koprowsky and Lennette (1944) found that the pathogenesis of the infec tion produced by the Venezuelan equine encephalomyelitis virus in chick embryos is similar to that of the Eastern and Western viruses There was no change in the virulence of the virus for mice as a result of membrane passages

One might expect that the clinical and histologic pictures of lethargic or any other forms of encephalitis would be affected by the duration of the disease the age of the patient the virulence of the infection and other factors Though a number of clinical varieties of epidemic encephalitis have been recog nized—hyperkinetic delirious tabetiform and other types—there is no mani fest pathologic difference

Hassin (1933) says that the specific feature of typhus encephalitis is an abundance of nodules and their widespread dissemination which spares no part of the nervous system The same may be said of the ganglion cell changes Ganglion cell changes occur throughout the brain and may be either mild as in encephalitis or very severe as in poliomyelitis

The nodules so much in evidence in typhus encephalitis are also very prominent in encephalitis which occurs in malignant endocarditis

Trichinosis encephalitis is a rather rare form of meningoencephalitis It shows a combination of mesodermal and degenerative phenomena Both are due to invasion by Trichinella larvae which can be demonstrated in the tissues of the brain or within the meninges

In rabies the central nervous system is in a state of inflammation a di seminated encephalomyelitis with the presence of Negri bodies The inflam matory foci are the same as in lethargic encephalitis

immune sera (1) Venezuclin equine encephalomyelitis virus is not related to either the Eastern or Western viruses, (2) two strains of the Western type differ in their capacity to develop the complement fixing antibody (3) the relationship between the Eastern and the Western types is doubtful Cross reactions rarely occur in 1:2 and 1:4 dilutions more often they arise in the same dilutions as nonspecific partial reactions since in that zone other antigens as well are reactive with the same sera

Casals (1945) reports that avirulent lyophilized antigens that ritiin their properties specificity antigenicity and lack of anticomplementary power for at least two years can be prepared with the Western type virus

At present the antigens of the Western type Eastern type lymphocytic choriomeningitis and St Louis viruses should be used as a routine practice* If the serum is anticomplementary or if a nonspecific reaction occurs the test should be repeated with serum inactivated at 56° C for twenty minutes If this procedure does not eliminate the nonspecific reaction the serum must be classified as unfit for the test

Guinea pigs are highly susceptible to Venezuelan Eastern and Western equine encephalomyelitis viruses From these animals hyperimmune sera can be obtained

ST LOUIS ENCEPHALITIS AND LYMPHOCYTIC CHORIOMENINGITIS

St Louis virus is pathogenic for mice and hamsters these two species are used for the production of hyperimmune serum for the St Louis and lymphocytic choriomeningitis viruses Casals (1945) has prepared hyperimmune sera which following inactivation at 56° C for 20 minutes had titers of 1:64 to 1:128 The serum is heated at this temperature following dilution *in order to prevent coagulation Sometimes a partial nonspecific fixation* of the complement occurs with the dilutions 1:2 and 1:4

Lymphocytic choriomeningitis hyperimmune sera have been obtained in mice only

PATHOLOGY

Encephalitis is the term commonly used for nonpurulent inflammation of the brain Only those clinical cases with virus etiology will be discussed According to Hassin (1933) in epidemic or lethargic encephalitis the ecto-dermal and mesodermal tissues of the brain are involved including the meninges pia arachnoid The meshes of the pia may be greatly distended and *may contain hematogenous elements mainly lymphocytes and plasma cells* Quite numerous around the congested and hyperemic blood vessels they are often mixed with fibroblasts polyblasts macrophages and rod cells The in-filtrating cells are present throughout the pia that is around every part of the brain especially around the cerebellum

Frequently the subjacent cortex is also infiltrated but *in general the* vascular changes here are milder than in the pia They are more marked in the subcortical areas mainly around the smaller veins Here the vascular infiltrations for instance may be so marked that the lumina of the blood

*Editor's note (O F) Obtainable from Lederle Laboratories Inc. and from Markham Laboratories

ck activity It has been estimated to be 15 to 20 mμ in size The virus is uickly destroyed at room temperature but may be preserved for considerable me at low temperatures It can be easily preserved in 50 per cent glycerin t 4° C

According to Merchant (1942) this disease may be easily transmitted y various means under experimental conditions to sheep and less regularly, o cattle goats and swine The virus has also been transmitted to monkeys ice and field voles Under experimental conditions the incubation period ap ears to vary from 5 to 9 days after intracranial infection Cases of human fection have been recorded as mild and of short duration followed by omplete recovery Sheep exposed to this disease under natural conditions sually show clinical symptoms in from 6 to 18 days The onset of the disease characterized by a high temperature and symptoms of a central nervous sturbance Progressive incoordination tremors clonic muscular spasms nd paresis are often observed Recovery often occurs without the develop ent of nervous symptoms Permanent irregularities in locomotion may ollow the manifestation of severe nervous symptoms Animals which have covered from this disease developed complete immunity

The Russian spring summer encephalitis differs from the remainder of is group principally in respect to paralytic manifestations Shoulder girdle aralysis or paresis is reported to occur quite frequently Virus has been olated from the blood the cerebrospinal fluid and the urine of infected per ns Case fatality rates average about 30 per cent The Russians have effec vely used a formalinized tissue vaccine to protect man in the areas involved

The name Japanese B encephalitis has been used to distinguish from the on Economo type which the Japanese called type A an epidemiologically nd clinically distinct type of epidemic encephalitis Hammon and Reeves 945) stated that they have demonstrated the ability of six species (three nera) of California mosquitoes to transmit the Japanese B virus to animals nd have demonstrated its presence in the blood of inoculated chickens The apanese and Russians themselves have reported transmission by only five ecies (two genera) This disease did not attract much attention until the eat epidemic of 1924 which involved over 6 000 persons with 3 797 reported aths Since then annual epidemics have been recorded sometimes from umerous regions Between 1924 and 1937 from Japan alone 21 355 cases ith 12 159 deaths were reported Case fatality rates have ranged from to 75 per cent Epidemics or sporadic cases have also been reported om Formosa the Southern Ryukyu Islands eastern China and the eastern S S R Smithburn and Jacobs (1942) reported as a result of serologic tests at ' the St Louis and Japanese B' viruses have been active over broad panses of territory in Central Africa Sabin (1943) reported a number positive serologic tests for Japanese B virus in the Cincinnati area

Smorodintseff et al (1940) had already shown that the Russian spring mmer encephalitis is different from the autumn encephalitis which is

CULTIVATION, TREATMENT, AND IMMUNOLOGY

Carneiro (1944) tested duck and goose eggs as to their suitability for virus culture The results were identical with those obtained with chick embryo

Intraperitoneal neutralization tests with the Venezuelan equine encephalomyelitis virus were found by Lennette and Koprowsky (1944) to be feasible in mice as old as 200 days Inoculations of serum virus mixtures subcutaneously into 3 day old mice, or intraperitoneally into 8 day old mice provided a highly sensitive means for detecting antibodies to the St Louis encephalitis virus. Tests in mice 14 or more days of age were less sensitive or not feasible With the viruses of Eastern and Western equine encephalomyelitis Japanese B encephalitis and West Nile disease, a highly sensitive test was afforded by the use of mice up to 14 days of age Tests in 21 day old mice were less sensitive or inadvisable because of lack of uniformity in the results Present evidence suggests that subcutaneous inoculation of test mixtures into 3 day old mice may constitute a more sensitive quantitative test than does intraperitoneal inoculation into older, but still highly susceptible, mice Where adequate susceptibility to extraneural (subcutaneous or intraperitoneal) infection exists this route of inoculation of serum virus mixtures is much more sensitive for the demonstration of neutralizing antibodies than the intracerebral route

Treatment

Supportive treatment mainly large volumes of physiologic salt solution fortified with glucose and given intravenously is indicated to overcome dehydration Medicinal treatment is largely symptomatic and should be conservative Good nursing is essential It is reported that lumbar puncture gives marked relief of headache

Immunization is very effective in animals Due to the number of deaths which have occurred among personnel working with these viruses, it is now general practice to vaccinate at least once yearly all laboratory workers employed in the manufacture of encephalomyelitis vaccine

Davison (1941) and Gold and Hampil (1942) have tried serotherapy in human beings but the results are inconclusive

Stramonium and scopolamine are recommended for insomnia and for muscular rigidity and spasm They act as cerebral sedatives and hypnotics

OTHER VIRUS DISEASES

Russian spring summer encephalitis occurs annually in forest regions of the eastern U S S R and to a lesser degree in European Russia It occurs only during the spring and early summer coinciding with the activity of ticks The virus has been isolated from man rodents, and ticks Casals and Webster (1943 1944) have shown it to be very similar to or identical with the virus of louping ill of sheep in Scotland also known to be tick borne Silber and Shubladze (1945) have reported that louping ill is the tick borne encephalitis of western U S S R but that a different virus is responsible for tick borne encephalitis in the Far Eastern area The tick is not only the vector but also the reservoir since transovarian passage of the virus normally occurs

Louping ill is transmitted by the sheep tick Distribution is limited to tick infested areas and its seasonal occurrence in April May, and early June and again in September bears a close relationship to the months of greatest

TABLE XIV—THE "ENCEPHALITIS" GROUP OF VIRUSES AND VIRAL DISEASES
(According to Felsenfeld)

VIRUS	MORTALITY AND UNUSUAL CLINICAL PICTURE (IF ANY)	VECTOR TO MAN	ANIMAL RESERVOIR	VECTOR TO ANIMALS	VIRUS ISOLATED FROM BLOOD AND C S F	EXPERIMENTAL ANIMAL TO BE USED	NEUTRALIZED BY SERUM AGAINST	NEUTRALIZES VIRUS	REMARKS

Australian X disease	High	?	Monkeys	?	?	Monkey	Probably related to Japanese B		Virus was lost

identical with the Japanese B type Sabin (1943) reported the elaboration of a vaccine for experimental use in man

According to Grieg (1933) the virus of louping ill of sheep is transmitted in nature by certain ticks (*Ixodes ricinus*) Alexander and Neitz (1933 1935) transmitted the disease from infected to normal sheep by the nymphs of other ticks (*Rhipicephalus appendiculatus*) infected as larvae and by adults infected as nymphs This worker was unable however to demonstrate virus in eggs or larvae obtained from infected females The virulence of the infection appeared to be increased by passage through the tick hosts Smithburn et al (1940) isolated a virus which they have called the West Nile virus,' by the intracerebral inoculation of mice with serum from a mildly febrile woman in Uganda Africa It produces encephalitis in the mouse the monkey and the hamster Philip and Smadel (1943) have transmitted the virus in the laboratory by the bite of *A albopictus* mosquitoes The virus is related immunologically to the St Louis-Japanese B group Smithburn and Jacobs (1942) believe that the antibodies are specific for this virus in man

Bugher et al (1944) have isolated two unidentified viruses by the intracerebral inoculation of mice from mosquitoes caught in Colombia They called the viruses Sabethine I and Anopheles I from the genus of mosquitoes from which they were isolated

Hammon and Reeves (1945) in the summer of 1943 isolated from *A dorsalis* mosquitoes caught in Kern County California an unidentified virus (BFS 91) which produces encephalitis in mice cotton rats and hamsters and which can be cultivated by various methods in the chick embryo Sera from a number of encephalitis patients and from domestic and wild animals from the area in which it was found have neutralized it in protection tests In 1944 from the same area and from the same species of mosquitoes another virus (BFS 283) was isolated which also has proved to be difficult to identify and in all probability is identical to BFS 91

Evidence is therefore accumulating that there are a large number of arthropod borne neurotropic viruses of man and other animals and that they are of world wide distribution and of no small importance

The term acute lymphocytic choriomeningitis was suggested by Armstrong and Lillie (1934) This condition was formerly referred to as acute serous meningitis idiopathic meningitis acute benign lymphocytic meningitis meningitic form of encephalitis and acute aseptic meningitis

Armstrong and Lillie (1934) recovered an undescribed filtrable virus from a monkey to monkey transfer of infectious material from the brain of a patient who had died of encephalitis during the St Louis epidemic of 1933 Inasmuch as this virus is immunologically distinct from the encephalitis virus, producing in experimental animals an infiltration of round cells in the meninges and choroid plexus they designated it the virus of experimental lymphocytic choriomeningitis Scott and Rivers (1936) described a method of obtaining the virus from the cerebrospinal fluid and demonstrated that their virus likewise produced a characteristic histologic pattern in animals and was serologically

identical to the virus recovered by Armstrong and Lillie, as well as to the virus which Traub (1935) demonstrated in his colony of normal appearing white mice

According to Blackfan (1940), lymphocytic choriomeningitis in man is a benign disease It attacks both sexes As to age incidence, the patients are about equally distributed in each decade up to 40 years except during the first decade, when there are very few cases The majority of patients with the meningeal form are under 40 years of age Children are only exceptionally affected It is apparently a seasonal disease, as the majority of cases occur during the winter and spring months

In accounting for the relatively high immunity among older individuals as contrasted with the relatively low immunity of persons under 17, Armstrong and Wooley (1937) suggest that immunization of older individuals may have occurred during an epidemic seventeen years or more before, thus leaving a large number of persons under 17 years of age susceptible to infection with the specific virus

According to Blackfan (1940), while conclusive proof as to the portal of entry of the virus of lymphocytic choriomeningitis in human beings is lacking the basic evidence at the present time seems to point to droplet infection from the upper part of the respiratory tract, in both the meningeal and nonmeningeal forms of the disease A number of closely allied or identical strains of the virus of lymphocytic choriomeningitis have been described in different places throughout the United States, England, and the European continent

Blackfan (1940) stated that the onset of lymphocytic choriomeningitis often is preceded by signs referable to a minor respiratory infection, commonly called "flu" "grippe," or "cold" The symptoms usually subside before signs of meningeal irritation make their appearance—a severe headache beginning insidiously or abruptly

Lillie and Armstrong (1945), who studied the pathology of lymphocytic choriomeningitis in mice stated that the more striking gross and histologic observations in mice are polyserositis with serous exudate involving the pleura and the peritoneum Fatty degeneration of the liver, and, to a lesser extent, of the kidneys, appears as early as the third day and persists into the third week Focal necrosis occurs in the liver and, rarely, in the adrenal cortex and the corpora lutea More diffuse and irregular but sometimes focal necrosis is seen in the thymus, the spleen, the lymph nodes, and the bone marrow Scattered capillary thrombi occur in the liver and other viscera Generalized lymphocytic infiltrations, sometimes including larger lymphoid and plasma cells, some macrophages, and fewer polymorphonuclear leucocytes, involve serosal tissues of the pleura and the peritoneum, the renal cortex and pelvis, the liver, the salivary glands, the pancreas, the lungs, the heart, the adrenal glands, and less frequently, the tissue of the rest of the gastrointestinal genitourinary tracts, as well as the originally reported locations of the meninges, the choroid plexus, the ependyma, and in addition the spinal ganglia From the fact that similar visceral lesions occur not only in mice but also in intracerebrally inoculated monkeys and guinea pigs, it appeared to Lillie and Armstrong (1945) that the visceral lesions are a general effect of the virus, not peculiar to any one species Since in mice such visceral reactions appear earlier and more often after other cerebral inoculation, and since natural routes of infection are generally other than neural, it appears that spontaneous infections should produce visceral lesions proportionately more often than cerebral inoculation does and that such lesions might well dominate the pathologic picture in natural infection

Virus B	High Ascending myelitis	?	Monkeys	?	Yes	Monkey IC and IO	Related to herpes simplex and may be identical with W virus		Inclusion bodies, only laboratory infection in man

Alice (1945) in Bahia isolated from gray mice a virus similar to that of the lymphocytic choriomeningitis, and with the virus infected guinea pigs intracerebrally and intraperitoneally Rabbits and cats are refractory Convalescent serum from guinea pigs neutralizes the virus of the lymphocytic choriomeningitis

CHAPTER 22

LYMPHOGRANULOMA VENEREUM

JUAN I SOTO ROZAS

Synonyms—Climatic bubo sixth venereal disease Nicolas Favre disease bubo te inguinal lymphogranulomatosis subacute inguinal lymphogranulomatosis of intraglandular purulent foci lymphogranulomatous type of inguinal adenopathy benign inguinal lympho granuloma poradenolymphitis subacute inguinal poradenitis poradenitis subacute inguinal lymphadenitis lymphogranulomatosis inguinalis lymphogranulomatosis of the inguinal gland inguinal lymphogranuloma benign inguinal lymphogranuloma venereal lymphogranulomatosis venereal lymphopathy fourth venereal disease poradenitis nostras (Stannus Shannon 1933)

DEFINITION

Lymphogranuloma venereum is a generalized disease It is acquired like syphilis usually by sexual contact It is principally genito rectal with preference for lymphatic and nervous tissues with possible invasion of other organs such as the digestive tract respiratory apparatus cerebrospinal axis and its sheaths joints blood vessels the eye in all its segments at times the heart ovary abdominal and pelvic peritoneum spleen and skin

FREQUENCY AND GEOGRAPHIC DISTRIBUTION

The disease is frequent in Mexico Of 1 618 cases of venereal disease registered at Central Military Hospital in 1 45 3 cases (3 per cent were lymphogranuloma venereum It has been calculated that in the Mexican Army the disease is present in a proportion of 1 5 per cent In the fourteen dispensaries of the Federal District which treat venereal cases and in Morelos Hospital Mexico City there were (1945) 133 patients with lymphogranulomatosis among the 6 698 dispensary venereal patients and 87 cases among 6 653 hospitalized patients The overall percentage thus is 0 96 per cent for civilians with venereal disease

In the United States of 3 000 patients admitted to the Ant Venereal Medical Center in Hot Springs Arkansas 1 6 per cent were lymphogranulomatous according to a report by Graham (1941) covering the period between 193 and 1939

It is not possible to submit exact data on the incidence of the disease for any particular region since the means for establishing a precise diagnosis have been inadequate until very recently and because in most countries there are no regulations to compel the reporting to health authorities of cases of this disease ... For many years it was held that lymphogranuloma venereum was an exclusively tropical disease and that it had extended to temperate regions It is now known that it is worldwide in its distribution although it is most prevalent in tropical zones

ETIOLOGY

This disease was unknown before 1913 as a nosological entity and therefore many etiologic agents were described ... Durand Nicolas and Favre of Lyon published in 1913 their remarkable work ... differentiating it clinically from other venereal

* Shaffer M F Jones H [illegible] McKee C M [illegible]

Fig 138—Similarities and differences among members of lymphogranuloma psittacosis group of infective agents (From Rake G Shaffer, M F Jones, H P, and McKee C M Unpublished data, courtesy of E R Squibb & Sons, New York)

diseases, and indicating its infectious and contagious characteristics In 1930 Sven Hellerstrom and Wassen showed that lymphogranuloma venereum is produced by a virus which is filtrable through Chamberland 13 and Berkefeld V filters It was not until 1935 that Miyagawa et al verified the existence of visible forms in tissues and secretions of infected organs The polymorphism of the agent has been verified (Coutts et al, 1938 1942 Herzberg r and Kohlmuller 1938) It was thought to follow a development cycle beginning with elementary bodies which grow multiply by division and collect in plaques and in turn into vesicles which disintegrate and release new elementary bodies which then infect new cells (Shaffer et al 1940)

Dimensions vary from a fraction of 1 micron to 4 to 6 microns exceptionally even larger Until recently the agent had not been cultivated on routine laboratory media but it had been transmitted to animals In 1930 Hellerstroem and Wassen inoculated monkeys intracerebrally in 193? Levaditi et al found the mouse to be more satisfactory Grace and Suskind (1934) introduced mouse brain antigen for use in the intradermal reaction of Frei (1925) This reaction the Frei test was originally carried out with pus extracted by aseptic puncture from softened buboes not due to secondary infection This antigen is now being replaced by mouse brain antigen and antigen made from chick embryo (Rake et al 1940, Shaffer et al 1943)

Rake and associates* noted the existence of similarities and differences between infectious agents of a group called the "lymphogranuloma psittacosis" group which includes agents of lymphogranuloma venereum trachoma inclusion conjunctivitis or blennorrhea psittacosis and human atypical pneumonia (also called virus pneumonia) acute meningopneumonitis and pneumonitis in rats (induced experimentally) Fig 138 shows the numerous similarities between lymphogranuloma venereum and psittacosis In a culture of psittacosis on chick lung violent Brownian movement was observed such as had already been seen in lymphogranuloma cultures In addition several investigators found in cultures on chick embryo that both agents (lymphogranuloma and psittacosis) have developed cycles so similar that the forms described for either could almost be mistaken for the other

The agent is susceptible to the action of sulfonamides It survives in suspensions of both brain and chick embryo in the frozen state It resists desiccation glycerin and freezing in vacuum but does not resist ultraviolet light 0 1 per cent formalin 2 per cent urea 50 per cent glycerin or ether

The discovery that individuals clinically not lymphogranulomatous react positively to the Frei test calls attention to the probable existence of a large number of latent and potentially dangerous infections in sexually promiscuous individuals However it is important to remember that a serologic relationship exists among the various agents of the lymphogranuloma psittacosis group Also on occasions when the Frei test might be of great value recent primary or secondary syphilis will give positive lymphogranulomatous reactions These reactions appear to be more sensitive than the intradermal reaction (Schaffer et al 1941) *It has been found in laboratory practice that* while the Frei test turns from positive to negative under treatment other reactions remain positive (Schaffer et al 1943) This does not coincide with observations made in our Lymphogranuloma Venereum Service in Central Military Hospital Here it has been found in a study of 22 cases (18 glandular and 4 rectal) that treatment by antigens or by sulfonamides does not influence positivity to the Frei test

*At the Squibb Research Laboratories.

Attention should be called to the vesicular reaction of Ottolina (1943) who experimented with cerebrospinal fluid concentrated in vacuum and injected intradermally This procedure produces a vesicle at the point of injection The results obtained were the same as with the Frei test

TRANSMISSION

Most frequent means of transmission is by sexual act whether normally or abnormally executed immissio penis in anum, suctio penis immissio linguae in genitalia mulieris oscula in anum alterium ejaculatio seminis alterius in os proprium semen devoret These practices whether contraceptional or perverted extend and spread lymphogranuloma venereum

In the male the primary lesion Bory chancre (Bory, 1921) is generally in the penis meatus or anterior urethra In the female it may be in the vagina cervix of the uterus labia majora and labia minora The localization of this lesion explains the gland invasion which follows as will be seen later

In the passive pederast the initial lesion is localized in the anus or in the rectum Coutts et al (1940) have cited cases of Bory chancre of the lips tongue and pharynx with cervical adenopathy lymphogranulomatous cheilitis marginal glossitis tonsillitis pharyngitis and laryngitis Perhaps the ingested microorganisms can cause lesions in the entire digestive tract

Other organs which may be affected include the spleen liver, eye (Coutts and Espildora 1934) by direct inoculation or by general invasion respiratory system (lungs) joints the cerebrospinal axis (Sabin and Aring 1942) perhaps even the heart and arteries (May 1944) and also the skin (Kleber 1930)

Laboratory workers have been infected by the sneeze spray of infected experimental animals In other cases the organism has penetrated through the skin on the hands (Harrop et al 1941)

PATHOLOGIC ANATOMY

Bory chancre is a plasmoma without polymorphonuclears with newly formed blood vessels near the surface, this distinguishes this chancre from the primary lesion of syphilis and from soft chancre

Microscopically the epidermis is thickened as are also the interpapillary prolongations papillae becoming thinned out there is infiltration between epidermis and dermis principally of polynuclear leucocytes filling the edematous epidermis Vessels are dilated with cells and intercellular spaces in edematous condition the clear limit between the epidermis and the Malpighian body cannot be seen the number of spindle cells is increased and they are in a state of division According to Favre (1930) there are no polymorphonuclears in the pathologic fluid for which reason he called the lesion a "plasmoma" In the center there is a microabscess similar to microabscesses of the glands in the walls of which are found epithelial cells polymorphonuclears and acidophilic mononuclears in great abundance, which enclose the Gamna corpuscles (Gamna 1923)

diseases and indicating its infectious and contagious characteristics In 1930 Sven, Hellerstroem and Wassen showed that lymphogranuloma venereum is produced by a virus which is filtrable through Chamberland 13 and Berkefeld V filters It was not until 1935 that Miyagawa et al verified the existence of visible forms in tissues and secretions of infected organs The polymorphism of the agent has been verified (Coutts et al, 1938 1942, Herzberger and Koblmuller 1938) It was thought to follow a development cycle beginning with elementary bodies which grow multiply by division and collect in plaques and in turn into vesicles which disintegrate and release new elementary bodies which then infect new cells (Shaffer et al 1940)

Dimensions vary from a fraction of 1 micron to 4 to 6 microns exceptionally even larger Until recently the agent had not been cultivated on routine laboratory media, but it had been transmitted to animals In 1930 Hellerstroem and Wassen inoculated monkeys intracerebrally in 1932 Levaditi et al found the mouse to be more satisfactory Grace and Suskind (1934) introduced mouse brain antigen for use in the intradermal reaction of Frei (1925) This reaction the Frei test was originally carried out with pus extracted by aseptic puncture from softened buboes not due to secondary infection This antigen is now being replaced by mouse brain antigen and antigen made from chick embryo (Rake et al, 1940 Shaffer et al 1943)

Rake and associates* noted the existence of similarities and differences between infectious agents of a group called the "lymphogranuloma psittacosis group which includes agents of lymphogranuloma venereum trachoma inclusion conjunctivitis or blennorrhea psittacosis and human atypical pneumonia (also called virus pneumonia) acute meningopneumonitis and pneumonitis in rats (induced experimentally) Fig 138 shows the numerous similarities between lymphogranuloma venereum and psittacosis In a culture of psittacosis on chick lung violent Brownian movement was observed such as had already been seen in lymphogranuloma cultures In addition several investigators found in cultures on chick embryo that both agents (lymphogranuloma and psittacosis) have developed cycles so similar that the forms described for either could almost be mistaken for the other

The agent is susceptible to the action of sulfonamides It survives in suspensions of both brain and chick embryo in the frozen state It resists desiccation glycerin and freezing in vacuum but does not resist ultraviolet light 0 1 per cent formalin 2 per cent urea 50 per cent glycerin or ether

The discovery that individuals clinically not lymphogranulomatous react positively to the Frei test calls attention to the probable existence of a large number of latent and potentially dangerous infections in sexually promiscuous individuals However it is important to remember that a serologic relationship exists among the various agents of the lymphogranuloma psittacosis group Also on occasions when the Frei test might be of great value recent primary or secondary syphilis will give positive lymphogranulomatous reactions These reactions appear to be more sensitive than the intradermal reaction (Schaffer et al 1941) *It has been found in laboratory practice that* while the Frei test turns from positive to negative under treatment other reactions remain positive (Schaffer et al 1943) This does not coincide with observations made in our Lymphogranuloma Venereum Service in Central Military Hospital Here it has been found in a study of 22 cases (18 glandular and 4 rectal) that treatment by antigens or by sulfonamides does not influence positivity to the Frei test

*At the Squibb Research Laboratories

Genito ano rectal lesions (*Jersild's syndrome*) are characterized by elephantiasic edema which deforms the organ In some parts these are infiltrated with tense superficial covering while in other parts there may be deep sclerous ridges There are hard or soft nodules fistulas indiscriminately scattered dry or suppurating In the female the vagina may be intact with at times slight infiltration If the rectum is invaded initial lesions are simply inflammatory later becoming sclerotic (cicatricial) with narrowing of the diameter of the organ generally in the area of from 3 to 4 cm from the anal

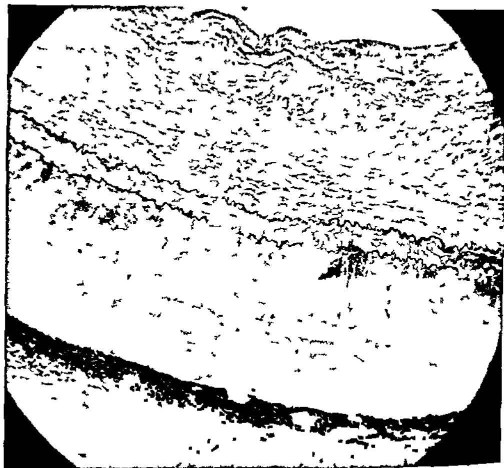

Fig 140—Marked endarterial thickening duplication and lack of continuity of internal tunica elastica (Photomicrograph by Mayor M C L Contreras R collection of Soto)

sphincter to about 8 or 10 cm that is the stenosis corresponds to the region of the glands of Gerota which in the female are anatomically located at this point Proctoscopically we observe red and violet colored mucosa edematous sometimes ulcerated vegetative and stenotic

Microscopically the lesions are such as are present in all forms of elephantiasis sclerosis new formation of connective tissue edema cellular infiltration vascular lesions granular tissue with enormous infiltration of leucocytes and plasma cells In some cases the infiltration is perivascular in others it resembles

Microscopic lesions in gland tissue show increased volume or glands adherent to each other and to surrounding connective tissue which is found to be infiltrated and hardened On extirpation there is obtained a hard fibrous mass softened in some portions and very vascular Superficial glands are small hard and reddish the inflammatory tissue which follows consists of large also hard wine colored masses with small abscesses in the center are two or more enlarged glands yellowish white and soft containing numerous microabscesses In sections we see fibrous filaments outlining small cavities filled with serum and pus In the interglandular tissue abscesses also exist with this difference they are larger and generally fistulous

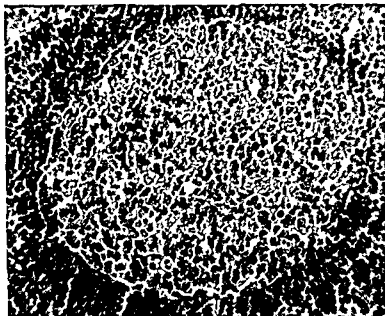

Fig 139 —Lymphocytic plasmocytic infiltration of connective tissue (Photomicrograph by Mayor M C F Contreras R collection of Soto)

Microscopic sections reveal the microabscesses limited by the epithelial cover In the glands can be distinguished the external cortical zone the internal cortical zone the intermediate zone and the central zone In the external cortical zone small nests of macrophages are found these have large *nuclei poor in chromatin* The *internal cortical zone* is a *fibrous skeleton* which forms large alveoli in the depth of which are found polynuclears lymphocytes and connective tissue cells The intermediate zones present multiple cellular elements remnants of polymorphonuclear leucocytes with fibrin among them The central zone is composed of unrecognizable cellular fragments made up of small clusters irregular oval round or elliptical scattered in a fibrous sheath Some of these elements have pyknotic nuclei (Phylactos 1922)

teristics help but little in making an early diagnosis in most cases since this type of lesion is not the most frequent (9 per cent) The most frequent form is the herpetiform chancre (73 per cent) which as the name implies looks very much like herpes with which it may be confused because of its ulcerative manifestations It is a very small chancre of brief duration sometimes fleeting so that unless the physician finds traces of it or unless the patient tells of having had the ulcer one might suppose that the adenitis was the beginning of the morbid process (bubo d emblee)

Next in frequency is the syphiloid form (12 per cent) This is so much like *a primary syphilitic lesion that according to Sezary it is frequently con*fused with it until typical adenopathy makes its appearance and establishes the differential diagnosis The syphiloid chancre an ulceration with an indurated base persists for several weeks when left to itself

Fig 14ª—Fluctuating lymphogranulomatous bubo (Photograph by O Pérez collection of Soto)

The chancriform type may be confused with soft chancre because of the *irregular ulceration with a soft base which heals in several* weeks leaving a scar It has a frequency of 6 per cent

Finally the infiltrating Bory chancre has the lowest frequency (3 per cent) according to Sézary Below the skin or mucosa which may be normal in color or reddish an infiltrated area may be noted upon palpation *It varies* in form and in dimensions may be thick or thin and the contour may be either regular or irregular

Bory chancre appears usually 20 to 40 days after inoculation The incubation period may however be shorter (8 to 15 days) Duration of the chancre depends upon various factors treatment virulence of the infectious agent infiltration of the lesion natural defenses of the patient It may be fleeting or it may last for weeks or even months

tuberculous follicles There are epithelial cells, giant cells surrounded by lymphocytes, and numerous plasma cells This process invades the dermis and cellular tissue, where we find edema, infiltration, and sclerosis The lymphatics are dilated and contain numerous lymphocytes and plasma cells Even when there is no elephantiasis, but only ulceration, there are always signs of sclerosis lymphangitis, and vascularitis, just as in elephantiasis

CLINICAL FORMS

Like syphilis, lymphogranuloma venereum also presents the primary lesion or chancre of inoculation and, later, various lymphatic, mucocutaneous, vascular, visceral osteoarticular nervous etc localizations so that this disease also presents the picture of general infection

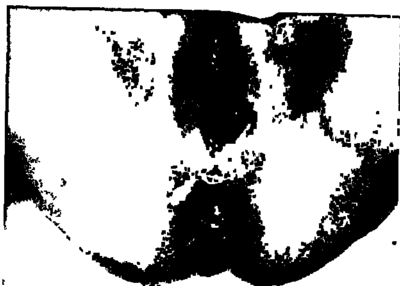

Fig 141 —Cicatrix of femoral ligature and extirpation of lymphogranulomatous glands (Collection of Soto)

The initial lesion or Bory chancre (Bory 1921 1924) presents unmistakable characteristics in its typical form, however it is frequently confused with soft chancre, the primary lesion of syphilis mixed chancre (Ducrey syphilis), or other venereal diseases Often this infection does not occur alone but simultaneously with another venereal disease (in association with the soft chancre of Ducrey, with syphilis, or with gonorrhea)

Sezary (1935) classified the initial lesion, on the basis of its appearance, into herpetiform, syphiloid and nodular chancres with three subtypes pure nodular, ulcerated and follicular nodular chancriform (like Ducrey's soft chancre), infiltrating

Pure nodular chancre is characteristic a rounded nodule 5 to 10 mm in diameter, painless but little inflamed firm, covered by normal colored or slightly pink mucosa, and lasting several weeks Unfortunately, these charac

A

B

Fig 143 —*A* *B* *C* Invasion of genitals and anus (Jersild syndrome) *D* Vulvar elephantiasis Perineal anal invasion (Photograph by O Peréz)

Although the most frequent localization of the initial lesion is on the penis it may also localize in the meatus the urethra the anus or the rectum or as in syphilis it may be extragenital

Meatitis described by Coutts presents a reddened meatus edematous and infiltrated generally to a moderate extent at times more or less inflamed Urethritis appears as mild (urethritis of Waelsch?) and asymptomatic showing a thin whitish or whitish yellow discharge with a few shreds in the urine collected in the first vessel Leucocytes epithelial cells and mucus are found No bacteria are seen but the secretion may be antigenic since it contains Miyagawa corpuscles or their products

The infection may spread from any of these initial lesions along the corresponding lymphatic vessels to the inguinal and iliac glands on both sides resulting in formation of various changes according to the location If it occurs in the lymphatic vesicles of the penis (truncal lymphangitis of May 1940) it is palpable It may form an abscess which discharges and leaves a fistula Another important sign described by May as quite frequent is what he calls early regional edema This is due to obstruction of lymphatic circulation and to lymphangitis When it localizes in the prepuce which becomes violet in color this author calls it violet edema of the prepuce According to other authors it may occur later as a sign of further outbreaks of the disease and should be looked for moreover in the penoscrotal angle in the pubis or hypogastrium and in the muscle (femoral triangle)

Within 1 to 6 weeks after the appearance of the Bory chancre we see inguinal adenitis unilateral or bilateral The tumor like mass is ovoid varying from the size of a pigeon egg to that of a turkey egg In some cases however the adenitis precedes by several days the Bory chancre or d emblée appears without this antecedent adenitis Inguino iliac adenitis may present various forms from syphiloid to abortive and may develop suddenly or slowly

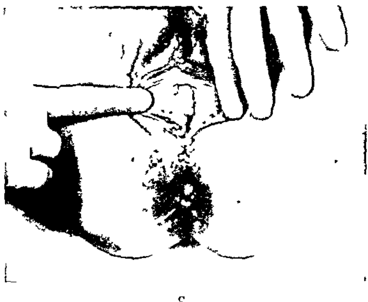
The patient experiences discomfort on one side of the groin or both on walking Glands are slightly enlarged hard isolated with one larger than the others with little or no pain (syphiloid adenopathy) A few days later periadenitis appears which unites the glands resulting in a hard formation which adheres to the skin This may extend toward the iliac fossa and embrace the iliac glands (in one third of the cases) constituting according to Sézary the pathognomonic sign Or it may extend toward the anterosuperior iliac spine and invade all the inguinal glands or toward Scarpa s triangle including the inferior or external group and the central glands (inguino central form)

In about one third of the cases this adenitis is bilateral It frequently begins on one side and then passes to the other with different characteristics Two to four weeks later the signs and symptoms are characteristic and well defined

1 Palpation with pressure upon these glands in spite of the appearance of acute inflammation elicits no pain (Favre s sign of glandular disturbance)

2 The entire mass can be moved *upon a deep plane* ("shaking sign" of Favre)

3 Color of the skin *changes from reddish to violaceous* (violet adenitis of Favre)



4 The periadenitis *upon infiltration of cellular tissue* gives a sieve like aspect to the mass (" accompanying cellulitis " of Favre)

5 When the *tumor like mass is palpated* softened spots are found in the midst of the hard mass these are small intraglandular or periglandular collections which *remain isolated* ("*suppurating pockets with hard margins*" of Favre 1931)

When these abscesses open spontaneously they leave multiple fistulae with thin viscous gummy serosanguinolent yellowish or whitish secretion *The intermediate* skin generally remains intact However there are cases in which this process is confused with adenitis due to soft chancre This con*fusion is caused as much by* the quantity as by the character of the pus (*sup puration in mass of Pautrier 1924*) If left to itself the adenitis terminates *in atrophy of the glands and in sclerosis* (after several months or even years) During the course of development of the adenitis various lesions can be found *in the same tumor like mass ranging from definitely hard all the way to* fistulas perforating through the softened areas At times (Soto 1945) al*though rarely the process invades the femoral vessels resulting in hemorrhage* and perhaps in death if application of a ligature does not stop the loss of blood *in time*

At times the infectious agent invades the genitourinary organs as a form *of lymphogranulomatous epididymitis* (Coutts) *with localization in the tail* which most frequently develops fistulae Or the invasion may take the form *of ulcerative leucoplastic or vegetating lesions in the urethra terminating* in most cases in stenosis of the canal These lesions may extend to the pos*terior urethra and to the vesical neck presenting corresponding* symptomatology (Baneiu Coutts and Opizzo 1939) In the genital apparatus further spread *appears later genital elephantiasis involving* the external organs male and female due to obliteration of superficial lymphatic vessels and invading the labia *majora and minora in the female* and the prepuce or the entire penis and even the scrotum in the male Sequelae in the male may be a continuation of the Bory chancre of a bubo an inguinal fistula or plastic induration of the penis (May 1940) with nodules or fibrous plaques in the median dorsal line of the penis in the septum intercavernosum These formations are due simply to Miyagawa corpuscles which are carried directly to the region by the lymphatic route or which proceed by continuity from urethritis littritis and periurethritis of the same origin May found CF positive results with the Frei reaction in 85 cases of this disease Finally the invasion may take the form of urethroperineal or urethrorectal fistulae accompanied by urethritis peri urethritis genital elephantiasis and at times rectal stenosis (vulvar esthiomene and Jersild s syndrome)

Rectal invasion may be a direct infection from abnormal sexual practices it may be an indirect infection from secretions clothing utensils *instruments*,

C

D

Fig 111 (Cont'd)—For legend see opposite page

The process begins with all the symptoms and signs of acute rectitis the etiologic diagnosis of which is of enormous importance If subjected to intense specific treatment *the disease can be cured in the majority* of cases and rarely develops into chronic ulcerative or vegetating forms or the stenotic form Aravantinos (1935) reiterates the importance of diagnosis and states *that the Frei test is indispensable* for every patient with acute rectitis The chronic ulcerative form the infiltrated or vegetating form lasts for several years In the majority of patients from 20 to 50 years of age the disease terminates with a stricture of the rectum which in the beginning is inflammatory and then cicatricial If not treated the prognosis is fatal Generally some intercurrent affection (cachexia and tuberculosis pyelonephritis bronchopneumonia) at times a complication (intestinal occlusion perforation of the intestine and peritonitis) results in death

Since this is a *general infection fever occurs irregular in most cases* it seldom reaches 40° C and occasionally passes unnoticed Other general symptoms common to all infections are anorexia prostration loss of weight *headache anemia etc*

There have been described rheumatoid painful manifestations arthralgia and cutaneous eruptions—the polymorphous and nodular erythema type scarlatiniform urticariform ecthymatiform pruriginous rash furunculosis hard nodules which soften resulting in fistulae which can be classified as lymphogranulomatous chancres

OTHER LOCALIZATIONS

Kitagawa (1934) on ophthalmoscopic tests of the eye in *thirty lymphogranulomatous* patients found peripapillary edema and dilatation and tortuosity of blood vessels in most of the cases American European and Japanese authors have identified the symptoms and signs found in lymphogranulomatosis with the oculoglandular syndrome of Parinaud Appelmans referred to the case of a young physician who was accidentally infected at the University of Louvain The Frei test was made repeatedly and gave constantly positive results Coutts and Sanders published the case of a patient with the oculoglandular syndrome of Parinaud in whom the Frei test was intensely positive and who improved rapidly under sulfonamide therapy Inoculations were made from a fragment of the diseased conjunctiva into the brains of a monkey and mice Antigens obtained from these tissues gave positive reactions in patients with lymphogranulomatosis (See Oliphant et al 1942)

McNie (1942) of New York discussed the same subject and stated that the disease was lymphogranulomatosis This could be demonstrated perfectly since Miyagawa corpuscles were found in the posterior surface of the cornea *in eyes experimentally infected* with the aqueous humor taken from patients with Parinaud s syndrome

Vergara Espino in an informal verbal communication before the Society of Gastroenterology *stated that the reddening of the papilla* which he

fingers, etc., or it may be a later complication of an old and forgotten Bory chancre or of a lymphogranulomatous meatitis or urethritis. With reference to the direct infection Quiroga (1940) published the results of investigations in collaboration with Lanza and Zuccari made in a prison in Buenos Aires. He made Frei tests on 100 prisoners, 20 of whom were pederasts. The results were positive in 7 cases of each group. In the normal group it was possible to find scars of old inguinal lymphogranulomatoses. In 7 sodomy habitues there were rectal manifestations of a lymphogranulomatous character which were not seen in any of the normal subjects. However, it is not to be assumed that every rectal lymphogranulomatosis is proof of pederasty. Bensaude, the *wizard of rectoscopy*, as he is called in Paris, and Lambling state that more than four fifths of such patients are passive pederasts (1934).

Fig. 144.—Jersild syndrome: genito-ano-rectal lesion; stenosis of the rectum. (Photograph by D. Pérez, collection of Soto.)

In these cases infection penetrates across the mucosa by excoriation or by simple inflammatory lesions to the lymphatic network of the rectum. The tissues first invaded are the submucous and the intramuscular; next involved is the tissue between the rectum and the perirectal fascia or the peritoneum; and finally tissue is involved which could be called extramural, around the rectal wall, which communicates with the glands described by Gerota 3 to 8 cm. from the anus. Great importance has been assigned to infection of the glands of Gerota, but at the present time Lavre states that rectal infection is very little adenophilic.

In addition to lymphangitis and adenitis there may be lesions of blood vessels (arteries and veins) and local inflammatory lesions which, acting upon one another, lead to similarity with ulcers and sclerosis production (Cohen, 1930). Savignac (1937) calls this form of rectitis "chronic stenosal venereal rectitis" because in many patients other venereal diseases exist, such as syphilis, soft chancre and gonorrhea.

In forms which have persisted for several months localization occurs i the joints in approximately one tenth of the cases The joints most frequentl invaded are in the order of frequency the wrist fingers elbows the ankle and the knees (Grace 1941) In some cases there is articular damage wit reddening and great sensitivity of the skin covering the region The artic lar elements are not destroyed however, and the function of the joint eventually completely restored when the disease has been cured althoug the resultant arthritis may persist for years or may at times cause invalidis if the disease itself has not been properly treated

During the period of invasion lymphogranuloma venereum present general phenomena which vary in different patients All however confir the fact that we are dealing with a generalized infection Among the mos frequent indications are headache fever chills sweating anorexia nausea vomiting weakness loss of weight and prostration Also common are mus cular pains and a feeling of tenderness in the muscles arthralgia rheumatoi pains both in active or passive movement either accompanied by or withou swelling or inflammation of the throat conjunctivitis or generalized rash

DIFFERENTIAL DIAGNOSIS

Lymphogranuloma venereum as with most genital infections may b acute or chronic Both forms may be confused with many local or genera febrile conditions because of the similarity of signs and symptoms for ex ample in acute affections of the digestive and respiratory systems The disease may be confused with other venereal diseases with tuberculosis Hodgkin s disease lymphatic leucemia tularemia filariasis actinomycosis dysentery ulcerative colitis etc

Table XV is a summary of the most important differential characteristics of some diseases which most frequently make the diagnosis of lymphogranu loma venereum difficult

LABORATORY FINDINGS*

The Frei test the complement fixation test and the Miyagawa corpuscles regarded as the organism of the disease have already been considered

The intradermal test of Frei is positive only at the peak of the allergic period that is when specific antibodies have been formed in the infected or ganism This usually occurs only about 2 weeks after inoculation although at times it can occur later so that it is not difficult to understand that the test is negative at the beginning of the disease The test may also give neg ative results during the menstrual period and in the not so rare cases of floral syphilis when the two diseases exist in the same patient at the same time It is said that the test remains positive for the duration of the patient s life

Interpretation of results should be made from the fourth day According to Sulkin (1941) the reaction appears in 24 to 48 hours reaching a maximum in 3 days after which it gradually decreases in intensity A positive reaction

*Antigens may be obtained from E R Squibb and Sons

had observed was due to mild neuritis without serious effect upon the field of vision or upon the acuteness of vision

In 1928 a case at the General Military Hospital was studied by the Chief of Ophthalmological Service the then Col M C Adolfo Viguri Viguri The patient a 45 year old woman had unmistakable antecedent history of inguino crural glandular lymphogranulomatosis About a month after the development of the disease disturbances in the left eye began oculopalpebral con*gestion sensation as if there were particles of sand in the eye, abundant yel*lowish suppuration and conjunctivopalpebral growths (papillomatous neo formations in crest like groups) principally in the lower eyelid which were not modified by antigenic treatment Harrop Rake and Schaffer (1941) described two cases of nasal laboratory infection from the sneeze-spray of in*fected rats Septic fever with chills was observed with sweating articular* rheumatism and headache pharyngitis or laryngitis and adenopathy of the neck These authors refer to another case in which infection occurred through the skin of the hands

Cases have been described of accidental infection of surgeons who later developed buboes in the axilla (Klotz, 1890) Primary lesions have been described on the tongue of one patient 3 weeks after he had practiced cunnilingus *Two small lesions appeared on the side of the tongue* and five weeks later a voluminous tumor developed in the neck glands (Stannus 1933) Chronic chapping of the lips thickening of the tongue, and cheilitis in persons who had practiced coitus ab ore have been described by Coutts and other venereologists as have glossitis marginata and lichen produced by the *agent of lymphogranulomatosis which also causes tonsillitis pharyngitis and* laryngitis Milian has reported cases in which aphthae and buccal and genital lichen were found together Brulé (1937) in Paris and Coutts in Valparaiso described myositis of the nucha in patients practicing suctio penis who presented the genito ano rectal syndrome of Jersild Coutts also observed *two cases of plastic linitis of the stomach with positive Frei test two cases of* lymphogranulomatous patients with ileo lentis and periduodenitis and other patients with duodenal ulcer

In addition Crohn et al found terminal ileitis also called regional enteritis to be a granulomatosis This may affect not only the small intestine but also the large intestine and might be confused with appendicitis (Crohn et al 1932) because of the pain and palpable swelling in the right iliac fossa Left alone it may lead to acute obstruction perforation of the intestine and formation of fistulae which open into the abdominal viscera or into the abdominal wall These cases were almost always found among young persons be*tween 20 and 30 years of age*

Goodman (1936) found ulcerative colitis and stenotic lymphogranulomatous colitis in the ascending transverse and descending colon Cases of meningoencephalitis have also been described (Sabin and Aring 1942) and spinal fluid from patients with lymphogranulomatosis has been used success*fully as antigen in the Frei test (Aleman Pérez)*

consists of a papule vesicle or pustule with a diameter larger than 6 mm (Grace 1939) According to our observations the reaction persists after the *fourth day* for several weeks A corresponding subject should always be used in carrying out the test so that unspecific reactions will be eliminated for these have a maximum diameter of only 6 mm and decrease after three days

The reaction is more intense in inguinal than in rectal cases it seems that the attack upon the skin by the infectious agents influences this

Although some investigators have obtained better results by *using mouse* brain antigen most of the American workers (Sulkin Rake and Grace and Greenblatt 1941 Mortara and Greenblatt 1943 Axelrod 1942) agree that *the chick embryo antigen Lygranum is superior to all others* for use in the Frei test and that this antigen constitutes a more satisfactory procedure in the diagnosis of lymphogranuloma venereum In a study made by our Service (Gonzalez *Tasso* 1941) of 105 cases at Central Military Hospital we reached the same conclusion

The sole disadvantage of this test is its delayed appearance Ravaut et al (1932) proposed a hemo reaction for an early diagnosis An active antigen is injected intravenously this produces a temperature of 39° to 40° C after 12 to 18 hours The fever remains for 24 to 48 hours and is accompanied by general malaise chills headache insomnia weakness arterial hypotension and leucopenia This test has one disadvantage it can be used only once A second test on the same patient with the same quantity of antigen gives a weaker reaction and it is necessary to give twice or four times the usual dose to obtain the same results Continued injections eventually have no effect It *is stated that this test is negative in all patients who are not carriers* of the lymphogranuloma agent which would give the test a specificity of 100 per cent Regarding its sensitivity (Flandin and Turiaf 1936) the test is positive in 97 per cent of the cases

As for the complement fixation test we repeat that in both primary syphilis and in neurosyphilis these tests may give false positive results The intradermal test made with a good antigen is of greatest value in these cases On the other hand lymphogranulomatous patients may exhibit false positive reactions for syphilis (Heyman and Webb 1946) The practical advantages of the complement fixation test are its simplicity rapidity the small quantity of serum required (1 6 c c) and its appearance one week after initiation of the symptoms The test can be carried out at the same time and with the same tube of serum as the test for syphilis made before marriage The patient is not required to return to the laboratory as he must for the intradermal test It appears then in general that this test would be more useful for learning the incidence of the disease among the general population since positive cases could be submitted to clinical examination and to the intradermal test This *would place a large number of cases of* lymphogranuloma venereum under sanitary control Most of these cases are unrecognized at the present time

The test for the neutralization power of the patient s serum (Levaditi et al 1932) has not as yet come *into common use The presence of* Miyagawa

DISEASE	ETIOLOGY	INCUBATION PERIOD	INITIAL LESION	INGUINAL ADENOPATHY	SPECIFIC TESTS
Lymphogranuloma venereum	Virus	Approximately 15 days	Herpetiform papules may be unnoticed	Generally unilateral (left sided), inflammation the size of fist or larger, reaches several glands, painful, characteristic violaceous discoloration of the skin, suppuration is frequent, fistulae are multiple, substance aspirated from the fluctuant glands does not contain bacteria unless secondary infection exists	1. Frei test with human, mouse brain, chick embryo antigens. Complement fixation test with chick embryo antigen
Syphilis	Treponema pallidum (Spirochaeta pallida)	[illegible] to 6 weeks	Characteristic soft chancre, hard-rimmed papules, appears at first as an umbilicated papule	Characteristic "Ricord's pleiades," glands of definite consistency, acute inflammation generally does not exist, suppuration very rare	1. Wassermann test. Kahn test. 3. Dark field examination may show treponemata*
Soft chancre	Hemophilus ducreyi	3 to 8 days	Painful ulcer with granular base, abundant pus, bleeds readily, lesions may be multiple due to autoinfection	Glands enlarge in approximately one third of cases, usually with acute inflammation, bubo often painful and tends to suppurate, forming one fistula	1. Ducrey bacillus found in the lesion. Ito-Reenstierna test positive
Gonorrhea	Neisseria gonorrhoeae	3 to 5 days	Characteristic urethritis with profuse suppuration	Generally appears after termination of urethral suppuration, may be unilateral or bilateral, rarely suppurates	1. Typical diplococcus found in pus. 2. The microorganism may be cultivated
Tuberculosis	Mycobacterium tuberculosis (Koch's bacillus)	Insidious	May be of three forms—(1) ulcer with excavated borders, miliary tubercles may be seen at its base, (2) with nodules of characteristic apple jelly appearance, (3) indurated lesion with fistulous apertures	Hard with well-defined inflammation, growing slowly and adhering to skin, glands open through simple or multiple fistulae discharging pus	1. Bacillus tuberculosis in pus. Biopsy shows characteristic tubercles. 3. Tubercle bacillus may be injected into animals experimentally
Inguinal granuloma	Donovan bodies	3 to 6 weeks	Ulcerated papule extends in serpiginous form, forms cicatrix in center, extending to periphery	Inguinal lymphadenitis occurs only when secondary infection of the initial lesion exists	Donovan bodies found in scrapings from lesions, pathognomonic cells with foamy cytoplasm containing cysts of Donovan bodies may be seen by using Wright or Giemsa stain
Malignant tumor	Etiology unknown	Insidious	Epithelioma appearing generally in patients past 40 years of age, granular ulcer which bleeds freely with hard base	Characteristic malignant invasion	Biopsy shows character of the malignant tumor

Some success on a lesser scale was obtained with sodium salicylate (Chevalier and Fichrer) iodine (Ravaut) xylol administered orally in capsules (Menéndez in El Salvador) copper ammonium sulfate (Carré) and injections of gold (Almquist Lepinay Kalz etc) before the era of the sulfonamide drugs

Early in 1938 attempts were made to evaluate the therapeutic power of the sulfonamides in the different clinical types of this disease In 23 cases of lymphogranuloma Gjuric (1938) successfully used continuous treatment with Fuadin and Prontosil and recommended an ointment containing 10 per cent *Prontosil* to be applied to the open bul oes Later many other authors tried various sulfonamides both on human beings and on laboratory animals notably guinea pigs and mice It was found that treatment of the laboratory animals with sulfonamides (Findlay 1940a and 1940b) reduced mortality rates from 84 to 49 per cent if the animals had received sulfonamide daily in their food

It was observed however that in practically no case did rats remain indefinitely free of all symptoms whether they had been treated or not This observation is important because in spite of the sulfonamide treatment the majority of patients persist in showing positive Frei tests and positive complement fixation reactions which indicates that the infection probably is still present in latent form and these individuals have been converted into the highly dangerous carriers (Jones et al 1941)

Several studies have been carried out to determine the therapeutic value of various compounds It may be stated that in vitro as in vivo sulfadiazine holds the first place in treatment followed by sulfathiazole sodium sulfanilate sulfaguanidine and sulfanilamide

Chloromycetin has been used with some success in this disease This product was initially obtained from a new species of soil organism isolated in Venezuela now designated as *Streptomyces venezuelae* It is identified chemically and is the first antibiotic to be produced synthetically on a practical basis *Chloromycetin in a dose of 1 0 Gm* every eight hours for 14 days has induced clinical cure although the elementary body may still remain demonstrable in the tissues

Since 1940 (Grace 1941) sulfathiazole has been used at the Grace Clinic in the following manner 1 5 Gm that is 3 tablets of 0 50 Gm each are given three times a day for two weeks for a total dosage of 4 5 Gm daily During the three following weeks 1 Gm or 2 tablets are given in the same manner The treatment is discontinued for 3 weeks and is then repeated for 5 weeks This 5 week period is not always necessary to terminate the treatment In lymphogranulomatous ophthalmia *sulfadiazine* (Oliphant et al 1942) has been used as follows 3 Gm (6 tablets) divided into 3 doses daily for 5 days with 3 days of rest then repetition of the treatment The patient is considered cured after he has taken 30 Gm of sulfadiazine Sulfanilamide has cured 80 per cent of inguinal cases in 6 weeks and the remaining 20 per cent in 16 weeks with a total of 52 Gm Rectal cases re

corpuscles in infected tissues as seen in secretions is to be considered diagnostic of the disease These corpuscles can be seen microscopically with certain stains—eosin methylene blue Macchiavello Giemsa Noble Inoculation of mouse brain and chick embryo may also be carried out to facilitate the search

The Schilling differential count should also be mentioned In our study results were as follows leucocytosis 77 per cent, decrease in red blood cells 55 per cent neutrophilia 41 per cent lymphopenia 45 per cent monocytopenia, 41 per cent Hyperglobulinemia was found in 48 per cent of the patients and hyperproteinemia in 16 per cent

TREATMENT

Treatment of this general infection is medical no matter what organs are attacked Quinine was used in 1879 in Hungary in the belief that malaria was being treated Prior to 1927 localizations in the glands were surgically handled while rectal lesions were confused with syphiloma ' of Fournier and the external genital lesions especially in females were confused with elephantiasis and so called 'esthiomene" of the vulva In 1921 Ravaut and Scheikewitch discovered certain lymphogranulomatous formations in pus and mistook these for amebae They treated 4 cases of gland fistula with emetine and obtained favorable results Ravaut (1921) concluded that emetine had cured his patients Rodriguez Meza (1936) in Mexico tried the treatment At the present time however it has fallen into disuse

In 1923 in Argentina Destéfano and Vaccarezza (1927) introduced tartar emetic in the form of intravenous injections The results were good This preparation has certain objectionable features it is unstable it is toxic and it is not well tolerated by some patients (nausea vomiting vertigo general malaise chills cough intense pain throughout the length of the injected member and later intense polyarticular pains muscular pain and general debility) For this reason other salts have been sought Neoantimosan was later named *Fuadin* Other products are Neostibosan Neostam and in France in 1934 Anthiomaline (lithium antimony thiomalate) (Sézary and Lacquet 1934)

Neostibosan has given better results than Fuadin (Lopez Fagelking 1934) Polak (1933) reported cures using Stibial Hissard (1933) reported cure of 2 cases of urethritis which he called benign subacute since the Frei test was negative

According to Laurens (1935) Anthiomaline administration cured 50 per cent of the cases or its use resulted in great improvement conducive to cure In 26 per cent of the cases partial improvement was effected, while in only 14 per cent fistula formation could not be avoided

It may be concluded then that preparations of antimony constitute excellent medication for this disease but the treatment is inconstant and fistula formation and recurrences induce one to believe that the treatment is not specific

"*Sulfavibus* (for local infiltration) 10 c c daily taking into account that this amount is equivalent to 3 Gm to be combined with oral treatment keeping in mind the patient s tolerance

"*Intramuscular Antigenfabre* (smaller doses must be used for intravenous injections) Initial dose 0 25 c c maximum dose 2 c c or more according to tolerance With reactivation of lesions dilute in physiologic saline 0 75 c c of saline for every 0 25 c c of antigen Apply two or three times a week (In Central Military Hospital up to 140 c c of Antigenfabre have been used) (Soto• 1945)

'*Repodral* Initial dose 3 5 c c continue with 5 c c until a total of 10 or 15 injections have been given After a rest period of 30 days (accumulation) another equal series may be used Never to be used simultaneously with sul fonamides (Peryassu 1939 reported good results) unless antigen therapy can be applied "

Manifestations of the disease to be treated are (1) abdominal iliac in guinal adenopathy (2) acute or chronic nonstenosing rectitis (3) chronic stenosing rectitis (Other localizations have not been considered in these soldiers although such localizations are frequently present in their associates)

Adenopathy should be treated with sulfathiazole and with antigen therapy (minimum treatment of one month) If it does not yield to treatment the affected tissues are infiltrated with 10 c c of Sulfavibus daily (Fluctuating buboes are to be punctured and a volume of Sulfavibus equal to the amount of extracted liquid is to be used)

Chronic rectitis not stenosing should be treated in the same manner except that in acute phases 2 Gm of sulfasuxidine instead of sulfathiazole are administered every 8 hours and a daily infiltration with Sulfavibus of the accessible affected parts is practiced with due regard to tolerance until clinical cure has been effected (In all cases of open lesions including rectal lesions surgical sulfathiazole powder should be applied)

Chronic stenosing rectitis Patients must be sent to a hospital for surgical treatment This consists of resecting the stenotic rectum with or without prior colostomy or simply making an artificial anus according to the state of the patient (Borjas 1942)

Jersild s syndrome and elephantiasis in women are treated by infiltration and by surgery carrying out the indicated operations in each case

quired 10 months with a total of 172 Gm to cure 39 per cent of the patients In one case 584 Gm were administered in the course of a year, without results

Gray and Barnes (1940) tried injections of Frei antigen subcutaneously and intradermally with good results Grace (1941) used intravenous injections Prats (1939) used the same method of treatment but also used sulfonamide simultaneously The number of satisfactory results rose from 56 to 92 per cent Finally Bercovitz (1940) achieved success with intensive subcutaneous treatment He injected the antigen every 5 days increasing the dose from 0 1 c c up to 1 0 c c Best results have appeared in cases of rectal obstruction although slowly and gradually Treatment should last at least a year but the patient must be under observation for a much longer period

Kalz (1932) and Kalz and Sayler (1933) used injections of serum from lymphogranulomatous convalescents with better results than with Solganal radium therapy Neostibosan or surgical treatment On our Service blood injections from the patient himself as well as from other convalescents have been utilized rather successfully (Cruz Martinez 1939)

Sulfonamides have also been used parenterally Aleman Perez (1943) who originated the method in our country used first soluble sulfapyridine (Streptocid) then para aminobenzol sulfamido methylene sulfoxylate of sodium (Deseptyl) and last 30 per cent sulfamido succinate of sodium (Sulfavibus) at pH 7 0 The maximum injected dose of Streptocid was 3 Gm of Deseptyl up to 6 Gm and up to 9 Gm Sulfavibus were used in one injection It is necessary at the beginning of the treatment at the time of application to mix the product with cocaine to prevent pain (novocain must not be used because it forms a combination which may diminish the activity of the compound) Injections are made twice a week A decided improvement is observed after 6 or 8 injections Aleman Pérez treated 30 female patients with satisfactory results On our Service 50 patients with various localizations have been treated to date with very good results

The following therapeutics are used in the Mexican Army sulfathiazole sulfasuxidine sodium sulfamidosuccinate 30 per cent (Vibus Laboratories Mexico D F) Frei antigen for treatment called Antigenfabre (Vibus Laboratories) composed of a solution of infected mouse brain with the globulin mucoproteins and scleroproteins removed Antigenfabre in the form of an amino acid compound is dispensed in 10 c c ampule vials Norms have been established for the use of these products* and have been sent to all Military physicians of the Republic

Sulfathiazole Initial dose 0 10 Gm multiplied by 1/6 of the patient s weight Total dose in 24 hours 0 10 Gm multiplied by 2/3 of the patient s weight

Sulfasuxidine Initial dose 0 10 Gm multiplied by 1/3 of the patient s weight Total dose for 24 hours 0 10 Gm multiplied by the weight

*Oficio Circular Sanidad Militar Dirección Oct 1 1944 México D F

"*Sulfavibus* (for local infiltration) 10 c c daily, taking into account that this amount is equivalent to 3 Gm, to be combined with oral treatment *keeping* in mind the patient s tolerance

"*Intramuscular Antigenfabre* (smaller doses must be used for intravenous injections) Initial dose 0 25 c c maximum dose 2 c c or more according to tolerance With reactivation of lesions dilute in *physiologic saline* 0 75 *c c* of saline for every 0 25 c c of antigen Apply two or three times a week (In Central Military Hospital up to 140 c c of Antigenfabre have been used) (Soto 1945)

"*Repodral* Initial dose 3 5 c c continue with 5 *c c until a total* of 10 or 15 injections have been given After a rest period of 30 days (accumulation) another equal series may be used Never to be used simultaneously with sulfonamides (Peryassu 1939 reported good results) unless antigen therapy can be applied "

Manifestations of the disease to be treated are (1) abdominal iliac inguinal adenopathy (2) acute or chronic nonstenosing rectitis (3) chronic stenosing rectitis (Other localizations have not been considered in these soldiers although such localizations are frequently present in their associates)

Adenopathy should be treated with sulfathiazole and with antigen therapy (minimum treatment of one month) If it does not yield to treatment the affected tissues are infiltrated with 10 c c of Sulfavibus daily (Fluctuating buboes are to be punctured and a volume of Sulfavibus equal to the amount of extracted liquid is to be used)

Chronic rectitis not stenosing should be treated in the same manner, except that in acute phases 2 Gm of sulfasuxidine instead of sulfathiazole are administered every 8 hours and a daily infiltration with Sulfavibus of the accessible affected parts is practiced, with due regard to tolerance until clinical cure has been effected (In all cases of open lesions including rectal lesions surgical sulfathiazole powder should be applied)

Chronic stenosing rectitis Patients must be sent to a hospital for surgical treatment This consists of resecting the stenotic rectum with or without prior colostomy or simply making an artificial anus according to the state of the patient (Borjas 1942)

Jersild s syndrome and elephantiasis in women are treated by infiltration and by surgery carrying out the indicated operations in each case

CHAPTER 23

GRANULOMA INGUINALE

Robert B. Greenblatt

DEFINITION

Granuloma inguinale, as the name implies, is a granulomatous proce which usually occupies the inguinal region. It is a mildly contagious chroni and progressive autoinoculable disease involving skin and corium and occ sionally the lymphatics. The well known proclivity of the disease for the ex ternal genitalia has earned for it a place in the category of the venerea diseases. Its venereal origin, however, has never been absolutely prove (Greenblatt 1943)

ETIOLOGY

The etiologic agent of granuloma inguinale is the Donovan body o *Donovania granulomatis* (Anderson, De Monbreun and Goodpasture 1945) The disease has been reproduced in human beings by inoculation of aspirate pus from pseudobuboes of granuloma inguinale which contained no other organ isms than Donovan bodies. The Donovan bodies are strictly tissue parasites o man but have been successfully cultivated in the yolk sac of developing chicl embryos (Anderson 1943, Beveridge 1946, Dienst et al 1947), in yolk agar medium (Dienst et al 1948) and less luxuriantly in certain yolk free medi (Rake and Oskay 1948). The inoculation of this organism into volunteers how ever has not been followed by typical reproduction of the disease

INCUBATION PERIOD

Little is known about the incubation period of granuloma inguinale. The incubation period as recorded in various case reports in the literature varies from 8 days to 12 weeks. In the experimental production of the disease in human volunteers by inoculation of aspirated pus which contained only Donovan bodies the classic burgeoning granulation tissue so typical of the disease was apparent by the fiftieth day

EPIDEMIOLOGY

Granuloma inguinale is considered generally as a venereal disease and the consensus is that it is acquired by coitus. The frequency of a history of sexual exposure and the antecedent appearance of a primary penile lesion in the vast majority of males suffering from granuloma inguinale bespeaks a venereal origin for the disease. In spite of the fact that the lesions occur chiefly in the genital region some doubt exists as to its venereal origin

HISTOPATHOLOGY

Granuloma inguinale reveals in the pure or unmixed cases a uniform histologic picture. The essential features are (1) the massiveness of the cellular reaction in which the luxuriant granulation tissue is surcharged with plasma cells, *(2) the relative and conspicuous paucity of lymphocytes*, (3) the diffuse sprinkling of polymorphonuclear leucocytes with focal collections in the superficies and papillae, (4) the pronounced marginal epithelial proliferation simulating early epitheliomatous changes, (5) the pathognomonic large mononuclear cells scattered in various numbers throughout the granulation tissue.

The pathognomonic cell is specific for granuloma inguinale. The relatively large size of the cell, the diameter of which varies from 25 to 90 microns, *and the many intracytoplasmic cysts filled with deeply stained bodies are its* cardinal features (Pund and Greenblatt, 1937).

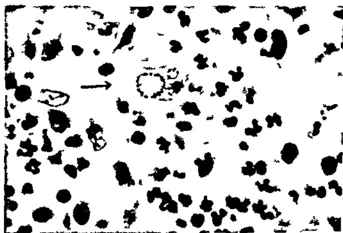

Fig. 14. Histologic section of granuloma inguinale showing pathognomonic cell. Arrow points to large mononuclear cell. (Reproduced through the courtesy of Pund, E. R. and Greenblatt, R. B., J.A.M.A. 108: 1401, 1937.)

COMPLICATIONS

Fusospirochetosis is the most common complication of granuloma inguinale. The lesions become ulcerative, progressive, foul smelling and painful and are often refractory to specific therapy. Syphilis, chancroid and lymphogranuloma venereum may be coexistent. Occasionally superimposed malignancy has been found to complicate the picture. Secondary elephantoid enlargement of the penis, scrotum or vulva and clitoris may occur.

DIAGNOSIS

The clinical picture may be so classical, the exuberant beefy red velvety tufts of granulation tissue so striking, that the diagnosis is unmistakable. Nevertheless, a diagnosis of *granuloma inguinale* should be made only when

Granuloma inguinale in this country occurs predominantly in Negroes In many instances its occurrence in white men or women definitely could be traced to sexual exposure to Negroes

CLINICAL SIGNS AND SYMPTOMS

The disease makes its appearance insidiously without premonitory symptoms or constitutional upset The disease begins as a vesicle papule or nodule The surface epithelium becomes excoriated or eroded leaving an ulcer with a beefy red granular base Early lesions have been observed to be small button like lesions raised above the surface or a fine granular film covering the glans penis with occasional nodules gently bulging the surface An early lesion which is frequently observed is a clean raised velvety smooth tuft of granulation tissue situated at the mucocutaneous border of the vaginal orifice at the preputial orifice or on the glans or inner surface of the prepuce The margin of the lesion is sharply defined The primary lesion in the female is usually found on the vulva or vagina Occasionally it is found on the cervix or in the perigenital zone The granulation tissue if traumatized bleeds easily The lesions are not painful which accounts for the fact that the patients rarely seek medical care early in the course of the disease The inguinal manifestations are secondary to the genital lesions Occasionally inguinal lesions appear without a trace of a genital lesion although a history of a previous genital lesion which healed spontaneously is frequently obtained

CLINICAL COURSE

The lesions show very little tendency to heal they spread by continuity or contiguity Extension is often slow showing only insidious progress Occasionally the spread is more rapid and there is a predilection for moist contact surfaces particularly in the crurosacral folds Daughter lesions frequently develop near the larger lesions These coalesce after a time to form extensive ulcerative processes The advancing border of the lesion has characteristic rolled edges the granulation tissue piling over onto the bordering epithelial surface

The ulcerative process may reach a stage where it remains more or less stationary for many years Secondary pseudoelephantoid enlargement of penis scrotum or labia may occur The lesions may show a tendency to scar formation at one margin and chronic progression at another Exacerbations of progression are common and sometimes so extensive as to occupy great surfaces The lesions when present for several months to years have a sour smelling peculiarly pungent characteristic odor

EXTRAGENITAL LESIONS

Most of the extragenital lesions are secondary to pudendal lesions although in a few instances purely extragenital lesions have been described Extragenital lesions occur in about 6 per cent of all cases of granuloma inguinale

PLATE IX.—Donovan bodies from spreads of lesion (granuloma inguinale).

Donovan bodies are demonstrated in spreads or when histologic study of biopsy reveals the pathognomonic cell

Spreads.—Spreads are made by obtaining a minute piece of granulation tissue *from the surface of the wound if it appears to be clean or from the* deeper part of the lesion if it appears to be markedly infected The exudate covering the infected lesions should first be removed The small piece of granulation tissue is best obtained with a sharp instrument such as a small bone curette The tissue obtained is smeared along several glass slides or crushed between two slides and then spread along the slide The slides are then dried and stained Wright stain has proved most satisfactory but Giemsa stain may be used to equal advantage The demonstration of Donovan bodies is possible in every case of granuloma inguinale

Fig 146—Donovan bodies from spreads of lesion (greatly magnified)

Biopsy.—When spreads fail to corroborate the clinical diagnosis one may resort to histologic methods Paraffin sections of biopsy material stained with hematoxylin (Delafield) and eosin or by the Dieterle silver technic will demonstrate the pathognomonic cell and the characteristic inclusion bodies with moderate ease in all cases of granuloma inguinale

TREATMENT

1 *Streptomycin*—1 Gm every 4 hours for 5 days for a total of 20 Gm is usually *sufficient to cure 90 per cent of the cases of granuloma inguinale* Complete healing usually takes place 1 to 4 weeks after cessation of therapy

Relapses will occur in 10 per cent Many of these (50 per cent) may be expected to respond to a second course of streptomycin

2 *Oral aureomycin* is a most effective antibiotic and even streptomycin *resistant cases have responded to this drug* (Greenblatt et al, 1948) The dosage is 250 mg capsules orally administered 4 *times* daily until healing is complete The usual dose required *varies from* 10 to 15 Gm Extensive cases may require *more*

3 *Chloromycetin* has been found to heal the lesions *in a* total dose ranging from 20 *to* 40 *Gm with lesions as large as* 70 *sq cm* The total dose has been *given* within an average of 12 days *Patients having had previous treatment* with other medicaments or surgery have responded to Chloromycetin In the event that examination of the tissue for Donovan bodies is still positive in a reasonable time or 5 to 7 days after Chloromycetin is started therapy should be continued until healing is complete

Greenblatt Wammock, Dienst, and West (1949) have reported excellent immediate results treating five granuloma inguinale patients with Chloromycetin These investigators have commented on advantages *in being able to give Chloromycetin orally* as *compared with streptomycin parenterally* and without appearance of nausea and vomiting even in the larger doses

4 *Antimonials*—The effectiveness of antimonial therapy decreases in direct *proportion* to the chronicity of the lesions Early granuloma inguinale responds rapidly to therapy with various antimony preparations *Tartar emetic* (1 per cent) may be given intravenously in ascending doses *beginning with* 1 c c and *increasing the dose by* 1 c c until a dose of 10 c c is reached It is administered every *2* or 3 days When the maximum is reached the dosage is decreased by 1 c c in descending strength until it is reduced to the initial dosage After a 2-week rest period, medication is again started Toxic manifestations such as joint pains, sore gums, anorexia, nausea, and vomiting are often *encountered with* tartar emetic Freshly prepared 1 per cent solutions are said to be more effective than stock ampules

Fuadin (Winthrop) *has proved to be superior to tartar emetic* It is more *convenient to administer and toxic reactions are seldom encountered* The solutions are stable and are available in 1 5, 3, and 5 c c ampules The initial dosage *of Fuadin is 1 5 or 3 c c* intramuscularly The dosage is then raised to 5 c c and given 3 times per week

Anthiomaline (Merck) is another stable and useful preparation that yields good results in a high percentage of cases It is available in 3 c c ampules and is administered intramuscularly 3 times per week Usually definite improve*ment in the lesions may be noted* within 4 to 6 weeks Either Fuadin or Anthiomaline should be continued until healing is complete Medication should then be administered at *weekly intervals for a period* of 6 months if recurrences are to be avoided If the lesions remain refractory to treatment then a change to streptomycin or aureomycin should be instituted

Donovan bodies are demonstrated in spreads or when histologic study of biopsy reveals the pathognomonic cell

Spreads—Spreads are made by obtaining a minute piece of granulation tissue from the surface of the wound, if it appears to be clean or from the deeper part of the lesion if it appears to be markedly infected The exudate covering the infected lesions should first be removed The small piece of granulation tissue is best obtained with a sharp instrument such as a small bone curette The tissue obtained is smeared along several glass slides or crushed between two slides and then spread along the slide The slides are then dried and stained Wright stain has proved most satisfactory but Giemsa stain may be used to equal advantage The demonstration of Donovan bodies is possible in every case of granuloma inguinale

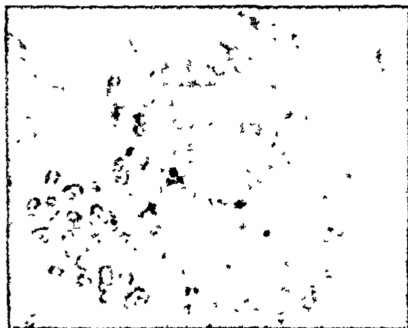

Fig 136—Donovan bodies from spreads of lesion (greatly magnified)

Biopsy—When spreads fail to corroborate the clinical diagnosis one may resort to histologic methods Paraffin sections of biopsy material stained with hematoxylin (Delafield) and eosin or by the Dieterle silver technic will demonstrate the pathognomonic cell and the characteristic inclusion bodies with moderate ease in all cases of granuloma inguinale

TREATMENT

1 *Streptomycin*—1 Gm every 6 hours for 5 days for a total of 20 Gm is usually sufficient to cure 90 per cent of the cases of granuloma inguinale Complete healing usually takes place 1 to 4 weeks after cessation of therapy

CHAPTER 24

DISEASES DUE TO BACTERIA—THEIR DISTRIBUTION AND OCCURRENCE IN THE TROPICS

OSCAR FELSENFELD

Bacterial infections usually enumerated among the tropical diseases are leprosy, cholera, shigellosis, salmonellosis, plague, tularemia, melioidosis and undulant fever. Leprosy belongs to the chronic granulomatous diseases and is caused by a Mycobacterium which, like the entire genus in which it is classified, is not strictly speaking, *a true bacterium or bacillus*. Cholera is evoked by a Vibrio, which again has a special taxonomic position. All other bacterial diseases enumerated in this group, with the exception of shigellosis, are primarily animal infections. They cause illness or carrier state in live stock, fowl, or rodents, and are transferred to man only under favorable conditions. Such circumstances arise *more frequently in the tropics*. Thus, the endemic and epidemic foci of these diseases are more frequently encountered in warm countries than in cold climates.

The principal factors which enhance the propagation of bacterial (and other) infections may be reiterated. Lack of personal cleanliness is favorable for multiplication of vermin and helps food contamination. Insufficient protection of water, milk, and food and improper preparation and lack of veterinary supervision of livestock cause the propagation of infections. Crowded and filthy housing supports the spread of disease from man to man. Where economic and social conditions and lack of education compel people to live under such circumstances, epidemics cannot be avoided. The temperature and the moisture of the tropics favor multiplication of the vectors and of the pathogenic organisms. Improper food and living habits, chronic devastating illnesses, and other factors which lower *the general resistance foster the* spread of bacterial diseases.

The absence of an adequate number of properly equipped and well staffed laboratories in numerous tropical regions, the indolence of certain governing groups, the lack of health education and mistrust toward the physician make it very *difficult in many places to draw a representative picture of the true* epidemiologic state. Many statistics are based on pure guesswork. Even such valiant attempts as that of McKinley (1935) to present the real state of affairs brought incomplete results, partly because of lack of *cooperation* and partly because data simply are not available due to the inadequate *laboratory and epidemiologic services* in several countries and colonies. During World War II the United States Army Medical Intelligence Branch collected priceless data from regions formerly closed to such investiga-

PROGNOSIS

Before the advent of streptomycin and aureomycin only 50 per cent of patients responded to therapy Recurrences in this group were quite frequent Neglected or therapy resistant patients often harbored the disease for 10 to 15 years With increasing age declining health and resistance there was a gradual activation of the lesions The ulcerations became so extensive as to occupy the whole pudendal region lower part of the abdomen buttocks and thighs The patients became anemic bedridden cachectic and finally died With streptomycin aureomycin and Chloromycetin hope may now be offered to every patient Cases resistant to streptomycin may be encountered but they are very few and these respond to aureomycin

CHAPTER 25

BRUCELLOSIS

Maximiliano Ruiz Castañeda

Brucellosis, also known as Malta fever or undulant fever, is an *infection* of domestic animals, mainly cattle, goats, and hogs. Because of the relationship between these animals and man, this infection is readily acquired by man. In animals brucellosis is characterized by its localization in the reproductive organs resulting in abortion. Abortion can also occur in human beings but is not a necessary sequela of the infection. The disease must be considered a bacteriemia with persistence of the organisms in various organs and tissues. This results in immunologic responses which cause characteristic symptoms.

Animals while showing the common effects of epidemic abortion are infected with Brucella types which are pathogenic for the respective species. Bovines are infected by *Brucella abortus* (Bang 1897), goats by *B. melitensis* (Bruce 1887), and hogs by *Br. suis* (Traum 1914). The resemblance of these bacteria to each other was pointed out by Evans (1918). Huddleson (1934) gave definite methods for differentiating them bacteriologically.

From a biologic point of view, each species of Brucella maintains its characteristics in each respective animal but under special conditions one species of animal may become infected with bacteria originally borne by others. This is of epidemiologic importance. Bovine stock, which under natural conditions are infected with *abortus* of low virulence for man, may acquire *melitensis* which has a higher infective power for human beings. From the clinical point of view, the three Brucella strains may cause similar symptoms in spite of different virulence so that all must be considered equally harmful.

GEOGRAPHIC DISTRIBUTION

Human brucellosis occurs throughout most of the world. The prevalence of a certain variety of the infecting agent in a specific zone depends fundamentally upon the proportion of the three species of domestic animals and the food habits of the population. *In regions where the beef industry is well developed, abortus is the most prevalent* (United States, Argentina, Uruguay, Cuba, etc.). In countries where goat's milk compensates for lack of cow's milk, the infection is caused principally by *melitensis* (Mexico, the Andean zones, and perhaps in the majority of the Latin American countries). *In countries in* which pork is the predominant meat, human infection with *suis* is frequent (*certain zones* of the United States).

The proportion of animals infected with Brucella is of secondary importance for the frequency of human brucellosis. In countries where adequate precautions *are taken* in the handling and distribution of milk, infection by *abortus* is reduced to cases in *rural* zones beyond sanitary control. In tropical countries, infection by *abortus* is of little importance because, since the colonial era, it has been the custom to boil milk to prevent

tions Some of them are already available (1944) and constitute excellent contributions to our knowledge of tropical infections The Bulletin of the Office of Inter American Affairs and numerous surveys carried out by the Rockefeller Foundation and other similar institutions greatly broaden the information available in this field of medicine

Only essential improvements work and more work in the tropical field can bring liberation from bacillary (and other) scourges of mankind

milk or a small piece of fresh cheese is sufficient to cause infection We recall a family of seven persons who acquired the infection simultaneously by eating a total of less than 100 Gm of goat cheese

PATHOLOGY

The presence of Brucellae in the cytoplasm of cells of the epithelial layer of the bovine placenta has been known since the work of Smith and Fabyan (1912) Goodpasture and Anderson (1937) and Buddingh and Womack (1941) presented important evidence in regard to the multiplication of Brucella within certain cells of the chick embryo when these organisms were inoculated on the chorioallantoic membrane An interesting finding has been reported by Meyer (1943) who found colonies of Brucella situated intracellularly in the cells of Bowman s capsule in a fatal case of *suis* infection

Nyka in our laboratory has not found intracellular Brucellae in man but his findings indicate the existence of intracellular organisms although in small numbers

It is evident that in the pathogenesis of brucellosis as suggested by Buddingh and Womack and by Meyer the intracellular position of the Brucellae plays a primary fundamental and important role in the mechanics of the infection as well as in the defensive processes a concept which must be taken into account in the diagnosis prognosis and treatment of the disease However we must not underrate the fact that Brucella can develop outside the cells especially within spaces destroyed by inflammatory processes and in fluids in various cavities

It is believed (Loeffler 1930 and most authorities) that histologic lesions found in experimentally infected guinea pigs show marked agreement with those found in man Lesions in the guinea pig were first described by Smith and Fabyan (1912) The infection produces changes similar to those of chronic lesions in tuberculosis These are observed in most organs in a perivascular or interstitial location The focal lesions consist of grouping of epithelioid cells surrounded by lymphoid cells The general aspect is that of a chronic granulomatous infection According to Hughes (1897) a large number of acute cases present no characteristic histologic lesions except in the spleen which correspond to lesions of the type observed in acute pyrexia

Sharp (1934) referred to the general appearance of the granulomatous infection and emphasized the tuberculoid form of the nodules the similarity being more marked when Langhans' cells are occasionally found but which show none of the caseation so characteristic of tubercular nodules

Meyer (1943) stated that cultures made from organs and tissues revealed considerable quantities of Brucellae especially noticeable in the kidney where the most characteristic lesions were found including the presence of Brucella colonies in the cells of Bowman s capsule This author noted massive infiltration of the stroma adjacent to the affected cells by monocytes lymphocytes plasma cells and occasionally polyblasts

spoilage In certain rural zones however milk is generally consumed fresh and raw The danger of consuming raw milk reaches incredible proportions in zones where rural populations must drink goat s milk (various regions of Northern Mexico) An important source of infection from both *abortus* and *melitensis* is cheese especially when it is freshly prepared The majority of cases observed in Mexico City are infections from eating goat cheese

TRANSMISSION

The mechanism of transmission of brucellosis to man is simple Bovine infection is readily acquired by persons who handle infected cattle through direct contact with infected membranes and perhaps by inhalation of dust

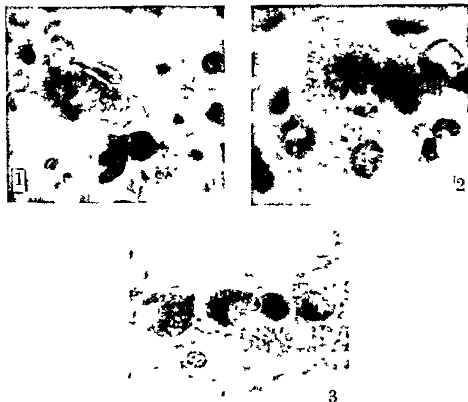

Fig 147—*1* Alveolar cell packed with *Brucella melitensis* Mouse inoculated intranasally (×1000) *2* Testis of guinea pig inoculated with *Brucella abortus* Interstitial cell (×1000) *3* Testis of guinea pig inoculated with *Brucella melitensis* Parasitized macrophages (×1000) *1* and *2* Nyka stain *3* Formalinized Clemes stain

containing Brucellae Purriel and collaborators (1944) attached special significance to these means of transmission giving them priority over infection by consumption of raw milk The most definite means of infection by *suis* is contact with *infected meat* *On the other hand a most important manner* of acquiring infection with *melitensis* is through the digestive system The virulence of this organism is such that in many cases a very small quantity of

ascertain whether that lesion was produced by Brucella or whether it w due to influences of cirrhosis of the liver from some source other than th organism

Kidney—The changes were the same as with *Br melitensis* (above)

Spleen—The spleen showed a great variety of lesions from the mos acute forms of splenitis with heavy congestion, dilatation of the sinuses swel ing of the splenocytes and a great number of polymorphonuclear leucocyte to chronic lesions characterized by a variable degree of sclerosis or by foci o necrosis with epithelioid and sometimes giant cells

Except in the liver Brucellae were regularly found in the lesions

In addition to these lesions which are considered characteristic o brucellosis many kinds of inflammatory localizations in various organs an tissues have been pointed out corresponding to the numerous complication of the disease These lesions have characteristics common to infections with out special structure varying from small cellular infiltrations to destructiv phenomena of great intensity

SYMPTOMATOLOGY

We do not wish to discuss the symptoms of brucellosis as presenting a over all picture in which the role of the specific type of Brucella has bee omitted This is often done because it is impossible to find clinical forms tha can be considered characteristic of each type of Brucella In fact the variou forms of acute brucellosis pointed out by Simpson (1940) may be caused by any of the three Brucellae This statement also applies to the insidious latent or chronic forms described by Evans (1934) as well as to the complication caused by localization of these organisms in various organs or tissues Our experience with cases principally those caused by *melitensis* has impressed upon us the necessity of considering the symptomatology as somewhat different from that described with respect to groups of patients infected by *abortus*

We wish to submit data on the incubation period of brucellosis and to present a description of the symptomatology in infection by *melitensis* as observed in over 900 patients Following this we wish to make a similar pres entation of infections by *abortus* availing ourselves of information from North and South American sources

Incubation Period—Information from various authors interested in de termining the lapse of time between exposure and appearance of the first symptoms gives an idea of the extraordinary irregularity of the incubation period There are variations which depend not only upon the type of in fective organism but also upon the virulence of each strain and the number of Brucellae which enter the body In some cases the symptoms appear a few days after exposure, in others they appear weeks months or even years later Severe infections with clinical pictures similar to influenza typhus or typhoid infections are seen when the periods of incubation are short On the other hand when symptoms appear after a long incubation period they are not striking The resulting clinical picture includes most of the chronic

Two fatal cases of acute brucellosis caused by *melitensis* studied in collaboration with Villasenor and Costero in this hospital showed but meager microscopic manifestations except in the liver, spleen and kidney, where red and white infarcts were seen with small subcapsular abscesses not larger than 2 millimeters. In one of the cases the lesions **in the kidney** were abundant, not in the glomerulus as described by Meyer but in the interstitial spaces. The inflammatory infiltrations were of variable intensity and location and contained numerous polymorphonuclear cells, lymphocytes, monocytes and polyblasts. Occasionally there were so many polymorphonuclears that an abscess-like appearance was given to the lesion. Numerous centers of infiltrated zones presented a definite necrotic aspect.

We found **in the spleen** zones of infiltration made up mainly of macrophages and lymphocytes but with numerous polymorphonuclears distributed not only in the infiltrated sites but also in a diffuse form throughout the entire organ. At several places groups of polymorphonuclears showed an abscess-like formation. Intense congestion was present, with enlargement of the sinuses and occasionally extravasation of red corpuscles.

In the liver numerous leucocytes were observed in the sinuses, as well as moderate lymphocytic infiltration in the space of Kiernan. Small lymphocytic infiltrations were found distributed throughout the organ. Small foci of necrosis and red infarcts, 2 to 3 mm., were observed. Many polymorphonuclears were seen within the infarcts. Mononuclear cells containing intraprotoplasmic formations which might have been Brucella colonies were observed in the spleen and liver.

It is of interest to add that positive cultures of various organs showed colonies from zones with microscopic lesions as well as from points where there were no lesions. The characteristic granulomatous appearance described by various authorities was not seen in these cases. On the other hand, in a chronic case of brucellosis described by Tovar (1943) and in one referred to by Costero (1945) there were found, especially in the spleen, nodular lesions made up of more or less numerous groupings of epithelioid cells surrounded by numerous lymphocytes, the general aspect of which was suggestive of tubercular nodules.

From the study of other cases, including the spleens of two splenectomized patients, Sisk found that the principal lesions are in the liver, kidney and spleen. The bone marrow was not studied.

Liver.—The liver showed interstitial hepatitis with enlarged intertrabecular spaces strewn with variable numbers of polymorphonuclear leucocytes, lymphocytes and plasma cytes. There was a marked hyperplasia of Kupffer's cells, the number was far greater than normally found. The liver cells in almost all cases showed a variable degree of fatty degeneration which usually affected the central part of the lobules. In some cases foci of necrosis were seen strewn in a random fashion all over the organ. A variable degree of cirrhosis was an almost constant feature, although it was not possible to

cases of *abortus* infection begin insidiously Chronic brucellosis sometimes called the Evans type is included in this group

Abortus infection with acute onset may be equally as severe as *melitensis* infection However in one group of cases observed in Uruguay (Purriel et al 1944) which presented clear evidence of the bovine origin of the infection the initial symptoms were not so striking While the fever was variable in form and intensity it was not sufficiently elevated so that several days or in some cases several weeks passed without any apparent need for hospitalization The clinical picture at this stage corresponds to that of influenza with marked asthenia Due to increasing general debility the patient prefers to remain immobilized When the fever is very high the physical and psychic states of the patient suggest a typhoidal condition Profuse perspiration persistent headache muscular pain usually in the flexor muscles of the legs neuralgia hyperesthesia and other nervous disturbances are concomitant symptoms Some cases show bronchial irritation and digestive disturbances accompanied by diarrhea or persistent constipation The acute phase lasts 8 to 15 days and even longer in some instances In the Purriel group of cases mentioned above improvement with complete recuperation was observed in uncomplicated cases When complications due to brucellary foci were present the clinical manifestations continued for a long time

Spink and Hall (1945) reported their observations on 35 cases which occurred in Minnesota where the infecting agent according to these authors was probably *abortus* since most of the patients had drunk milk from infected cows There were cases which began abruptly like influenza with or without gastrointestinal disturbances The fever showed a variety of forms and various degrees of intensity asthenia was marked as in the cases described by the Uruguayan authors and additional symptomatology was practically the same Other cases began insidiously In both studies in Uruguay and in Minnesota the benign tendency of the disease was marked

Although it is difficult to find many clinical descriptions of bacteriologically verified cases the impression one gathers from the literature especially the American literature is that the data presented here may be considered as the common picture of infection by *abortus*

In a comparison of descriptions of infections by *melitensis* and *abortus* it is evident that *melitensis* characteristically causes severe infections The infection begins acutely and is of longer duration than the acute phase of the infection caused by *abortus* In cases produced by *abortus* the illness frequently begins insidiously or with such minor symptoms that many cases are recognized only when they become chronic It is of interest also that in infection by *melitensis* headache is less frequent and gastrointestinal disturbances in acute cases are rare

Brucellosis Caused by Brucella Suis

This author is of the opinion in accord with reports from North American writers that the infection caused by *suis* is more severe than that caused by *abortus* and has a greater tendency to localize in the bones

brucelloses with insidious beginning. In our experience, principally with brucellosis of caprine origin, the most frequent length of the period of incubation is 2 weeks.

Following the period of incubation brucellosis may manifest itself as one of three fundamental clinical types: acute brucellosis, brucellosis with acute onset followed by a chronic phase, and chronic brucellosis with insidious beginning.

Brucellosis Caused by Brucella Melitensis

The early stage of the disease shows no difference from other acute infections, notably typhoid fever. In many cases the diagnosis is uncertain until the febrile period has extended beyond 3 weeks. During this phase many types of complications may occur. The process may vary from malignant brucellosis with a rapid and fatal termination to a benign form, at times amounting simply to an evening rise of temperature.

Fever may continue with a tendency to diminish in intensity for periods of time varying from 1 to 3 months. During this period a definite state of malnutrition becomes apparent. When the infection develops in patients under favorable conditions, symptoms are noticeably restricted; there are night sweats and pains in various joints, at times of extraordinary severity, particularly in the sacroiliac region, which necessitates immobilization because of pain. Frequently, when the patient submits to proper treatment, manifestations of the initial stage of infection gradually disappear. It is common, however, in acute cases, to find that the fever persists for 15 days to 2 months or more, followed by improvement with diminution or disappearance of the various symptoms. Improvement lasts from a few days to 2 weeks; this is followed by reappearance of fever, pains and frequently new symptoms. The fever may be continuous, intermittent, remittent or simply irregular; pains in the joints often become alarming. Among the various symptoms and complications which may arise, it is not unusual to observe orchitis, abortion, myositis, arthritis, osteitis, endocarditis and purpura. There is general debility with marked loss of weight, anemia, nervousness and mental depression, which is very characteristic. In this phase of the disease periods of relief may occur, even with disappearance of the symptoms. This fluctuation may end with marked improvement or more severe symptoms may set in, which may terminate fatally either from direct effects of the infection itself or from complications. The duration of this secondary period is variable. With the disappearance of clinical manifestations of the secondary phase the patient may become completely cured. Often, however, late manifestations appear, such as those listed, or other inflammatory changes may occur in any part of the body. The infection respects no organs or tissues.

Brucellosis Caused by Brucella Abortus

The infection appears in one of the three fundamental clinical forms indicated above. In contrast to cases of infection by *melitensis*, however, many

cases of *abortus* infection begin insidiously Chronic brucellosis sometimes called the Evans type is included in this group

Abortus infection with acute onset may be equally as severe as melitensis infection However in one group of cases observed in Uruguay (Purriel et al 1944) which presented clear evidence of the bovine origin of the infection the *initial symptoms were not so striking* While the fever was variable in form and intensity it was not sufficiently elevated so that several days or in some cases several weeks passed without any apparent need for hospitalization The clinical picture at this stage corresponds to that of influenza with marked asthenia Due to increasing general debility the patient prefers to remain immobilized When the fever is very high the physical and psychic states of the patient suggest a typhoidal condition Profuse perspiration persistent headache muscular pain usually in the flexor muscles of the legs neuralgia hyperesthesia and other nervous disturbances are concomitant symptoms Some cases show bronchial irritation and digestive disturbances accompanied by diarrhea or persistent constipation The acute phase lasts 8 to 15 days *and even longer in some instances In the Purriel group of cases mentioned* above improvement with complete recuperation was observed in uncomplicated cases When complications due to brucellary foci were present the clinical manifestations continued for a long time

Spink and Hall (1945) reported their observations on 35 cases which occurred in Minnesota where the infecting agent according to these authors was probably *abortus* since most of the patients had drunk milk from infected cows There were cases which began abruptly like influenza with or without gastrointestinal disturbances The fever showed a variety of forms and various degrees of intensity asthenia was marked as in the cases described by the Uruguayan authors and additional symptomatology was practically the same Other cases began insidiously In both studies in Uruguay and in Minnesota the benign tendency of the disease was marked

Although it is difficult to find many clinical descriptions of bacteriologically *verified cases the impression one gathers from the* literature especially the American literature is that the data presented here may be considered as the common picture of infection by *abortus*

In a comparison of descriptions of infections by melitensis and abortus it is evident that *melitensis* characteristically causes severe infections The infection begins acutely and is of longer duration than the acute phase of the infection caused by *abortus* In cases produced by *abortus* the illness *frequently* begins insidiously or with such minor symptoms that many cases are recognized only when they become chronic It is of interest also that in infection by *melitensis* headache is less frequent and gastrointestinal disturbances *in acute* cases are rare

Brucellosis Caused by Brucella Suis

This author is of the opinion in accord with reports from North American writers that the infection caused by *suis* is more severe than that caused by *abortus* and has a greater tendency *to localize in the bones*

CHRONIC BRUCELLOSIS

In infection produced by *Br melitensis* or *Br abortus* a chronic phase may follow the acute stage or chronic brucellosis may appear without an apparent initial attack

Differentiation between clinical manifestations of the various forms of chronic brucellosis is difficult In general chronic cases due to *melitensis* have previously presented an acute initial stage The symptomatology of chronic brucellosis is quite variable but generally it includes the following triad a febrile condition asthenia and subjective disturbances which are seldom explained by some organic lesion To this triad may be added manifestations due to complications caused by localization of the causative agent in various organs or tissues or to secondary infections that readily occur as a result of weakening of organic defenses

The febrile cycle at times assumes a special character which justifies the name undulant fever which has been given to brucellosis The undulations are due to the fact that periods of improvement and even of suspension of the symptoms are interspersed during the course of the disease The fever curve may assume various forms It may be intermittent remittent occasionally continuous sometimes showing only an occasional rise of evening temperature Loss of weight is proportionate to the intensity of the fever as is also the asthenia and psychic condition

COMPLICATIONS

So many complications may occur during the acute phase that space forbids a complete discussion of them in this chapter We shall therefore describe only those most frequently observed in our 900 patients infected with *Br melitensis*

Four cases of abortion were observed during the phase of invasion as well as several months after this stage On the other hand 3 women with chronic brucellosis had normal deliveries

Orchitis was observed in 14 out of 265 infected males This complication appears as an intense inflammation of the testis and epididymis sometimes affecting only the epididymis The inflammation appears as a redness with distention of the scrotum swelling being unilateral or bilateral Pressure on the organ results in intense pain When orchitis occurs during the period of subsiding fever and remission of the disease there is a severe febrile exacerbation which usually lasts for several days The course of this complication is relatively rapid it generally disappears in 1 or 2 weeks and seldom leaves any evidence of pathologic changes in the affected organ

Arthritis may appear in various joints The intra articular fluid is rich in Brucella but seldom has the characteristics of a purulent discharge Joint complications generally develop rapidly followed by complete functional recovery

A relatively frequent complication in infection by *melitensis* is a painful syndrome of the gluteal region which results in functional incapacity often requiring confinement to bed for weeks and even months there are grave consequences due to physical and mental depression Since there is no evidence of important involvement of the sacroiliac joint and since the pain is generally relieved by local anesthesia it is assumed that this trouble results from local inflammatory processes in the gluteal muscles or in their sites of insertion

Nervous disturbances have been observed during the acute phase Among these are encephalitis accompanied in one case under our observation by epileptiform attacks Myelitis radiculitis and neuritis have also been re[illegible] In spite of the severity of these manifestations patients usually make a complete recovery

Osseous complications should be listed among the most important manifestations of brucellosis Spondylitis and abscesses in the ribs have been observed with relative frequency We have not encountered inter[illegible] myelitis such as Harris (1941) described

We have seen less frequently many complications due to localization of Brucellae in various organs These have been described in detail by several authors Purpura described by several authors was observed in 20 of 600 cases in which the diagnosis of brucellosis was confirmed by blood culture In some cases purpura appeared after the ingestion of drugs in other cases after administration of vaccines or filtrates of Brucella in others the purpura was thrombocytopenic In 20 patients however there was no apparent cause to justify the occurrence of such a complication In these 20 cases purpura appeared in the lower extremities It was markedly symmetrical Brucellae were isolated by scraping these lesions which had resulted from bacterial embolism distributed over a peripheral capillary with local reaction enhanced by the allergic status of the patient

DIAGNOSIS

Brucellosis shows such variations in its clinical manifestations that it is not practical to attempt to make a diagnosis without recourse to laboratory tests Clinicians have for a long time depended upon the finding of agglutinins as the fundamental element in diagnosis There has been much discussion concerning the advantages and disadvantages of this method It is inadequate to depend entirely upon agglutination without using other tests In fact there have been cases of brucellosis with bacteremia in which the agglutination test for Brucella was negative, or of slight significance In chronic brucellosis according to Evans (1938) a marked percentage of individuals show no agglutinins

Our opinion is that for practical purposes agglutination test carried [illegible] out with sensitive and specific antigens are of [illegible] nizing the existence of the infection but als[illegible] of the disease and in guiding the treatment

CHRONIC BRUCELLOSIS

In infection produced by *Br melitensis* or *Br abortus*, a chronic phase may follow the acute stage or chronic brucellosis may appear without an apparent initial attack

Differentiation between clinical manifestations of the various forms of chronic brucellosis is difficult In general chronic cases due to *melitensis* have previously presented an acute initial stage The symptomatology of chronic brucellosis is quite variable but generally it includes the following triad a febrile condition asthenia and subjective disturbances which are seldom explained by some organic lesion To this triad may be added manifestations due to complications caused by localization of the causative agent in various organs or tissues or to secondary infections that readily occur as a result of weakening of organic defenses

The febrile cycle at times assumes a special character which justifies the name ' undulant fever which has been given to brucellosis The undulations are due to the fact that periods of improvement and even of suspension of the symptoms are interspersed during the course of the disease The fever curve may assume various forms It may be intermittent remittent occasionally continuous sometimes showing only an occasional rise of evening temperature Loss of weight is proportionate to the intensity of the fever as is also the asthenia and psychic condition

COMPLICATIONS

So many complications may occur during the acute phase that space forbids a complete discussion of them in this chapter We shall therefore, describe only those most frequently observed in our 900 patients infected with *Br melitensis*

Four cases of abortion were observed during the phase of invasion as well as several months after this stage On the other hand 3 women with chronic brucellosis had normal deliveries

Orchitis was observed in 14 out of 265 infected males This complication appears as an intense inflammation of the testis and epididymis sometimes affecting only the epididymis The inflammation appears as a redness with distention of the scrotum swelling being unilateral or bilateral Pressure on the organ results in intense pain When orchitis occurs during the period of subsiding fever and remission of the disease there is a severe febrile exacerbation which usually lasts for several days The course of this complication is relatively rapid it generally disappears in 1 or 2 weeks and seldom leaves any evidence of pathologic changes in the affected organ

Arthritis may appear in various joints The intra articular fluid is rich in Brucella but seldom has the characteristics of a purulent discharge Joint complications generally develop rapidly followed by complete functional recovery

Suspensions of dead Brucellae or their soluble products prepared by various technics are used as antigens Among the latter ' brucellergen prepared by Hershey and recommended by Huddleson (1934) and the extracts used by Morales Otero and Gonzalez (1938) are especially useful

Antigens prepared with whole Brucellae often cause very intense lesions at the site of the injection It is not unusual to observe inflammatory zones with necrotic centers These antigens may stimulate formation of agglutinins so diagnostic errors might be made at a later examination (Evans and collaborators 1938) For some years we have been using as a routine an extract obtained by partial trituration of a mixture of *Br melitensis Br abortus* and *Br suis* (Castañeda and Carrillo 1941) This product is diluted until definite cutaneous reactions are produced with 0 1 c c injected intracutaneously The test dose contains an insignificant quantity of antigenic material but this is insufficient to stimulate the formation of antibodies against the Brucellae

The local reaction is sufficient to be apparent even in persons of dark skin without however *producing necrotic* lesions

The cutaneous test is of great value not only for diagnostic purposes but also as a means of verifying epidemiologic data

The use of the intradermal reaction as the sole test in the diagnosis of brucellosis has been criticized and we are in accord with this point of view No test except the isolation of the organisms must by itself be considered as decisive The clinical study of a case must form the basis upon which all additional evidence in one sense or another may be built

Hematologic Studies

Our observations in a group of about 900 patients most of whom were infected by *melitensis* (Castaneda and Guerrero 1946) showed leucopenia in nearly one third and figures close to normal or above normal in the rest of the group The percentages of lymphocytes were higher than normally found with a corresponding decrease in polymorphonuclear leucocytes The increase in lymphocytes often in absolute numbers seems to indicate increased lymphogenesis in brucellosis On the other hand there seems to be an interfering effect in the yield of polymorphonuclear leucocytes which may be reduced in absolute numbers

As to the changes in morphology and other characteristics of white and red blood cells we have no data to indicate that this is of diagnostic interest in brucellosis Anemia frequently pointed out as a complication of the infection is related to the general status of the patient especially with respect to the intensity and persistence of the febrile reaction

Blood Cultures

Laboratory tests briefly indicated above constitute satisfactory proof of infection by Brucella when they are positive and in agreement with clinical data When they are negative they indicate absence of the infection But

Agglutination Test

Screening Test—The screening test is used as a preliminary test and may be performed at the patient's bedside A drop of antigen* is mixed with a smaller drop of blood taken by puncture of the finger or of the ear lobe A positive reaction shows blue clumps which separate completely from the red blood cells A negative reaction is characterized by a brownish green appearance Since the antigen is titrated to produce agglutination only when the agglutinins are at titers higher than 1 100 a positive reaction eliminates doubtful and negative tests

Negative reactions however are not considered as final until corroborated by the classical test tube reaction or by Huddleson's (1934) method

The screening test is especially valuable in rural zones where laboratory aid is not available

Titration of Agglutinins—Huddleson's rapid slide test is very useful as a diagnostic procedure and also as an indication of agglutinin content in the serum When it is desirable to determine agglutinin titers higher than 1 500 the tube agglutination method with suitable antigens is recommended

Differential Serologic Test—When a serum is positive it is our practice to use differential tests to determine the type of agglutinins present We use a substitute for the absorption method calling it the selective agglutination" method (Castañeda 1942) It is easy to demonstrate in a few minutes whether the serum is from infection by *abortus suis* or *melitensis* Identification has been completed in more than 600 cases of brucellosis where the selective agglutination test results have been checked by bacteriologic control

Opsonic Test

The opsonic test recommended by Huddleson and collaborators (1932) is an important indicator if systematically studied in each patient particularly when related to the numbers of available polymorphonuclear leucocytes It displays fluctuations often related to the condition of the patient it increases in intensity with recovery near at hand persisting after disappearance of the symptoms In order to prevent laboratory accidents by handling live Brucella we have recommended the use of formalin killed *Br abortus*

Allergic Test

This test determines hypersensitivity to Brucella or its by products It is carried out by means of intracutaneous injection of appropriate antigens In sensitive persons a cutaneous reaction occurs characterized by redness of the skin edema and painful sensation at the site of the injection Patients begin to show cutaneous reactions usually at the end of the first month of illness The reaction increases in intensity with the development of the disease often reaching a maximum months later and remains for indefinite periods

*We use an antigen suspension containing *Br abortus* and *Br melitensis* treated with 10 per cent formalin for 48 hours washed heavily tinted with methylene blue centrifuged and resuspended in 1 1 000 sodium citrate solution It is standardized with sera of known titers The concentration of the organisms is about 100 billion per cubic centimeter

drugs of uncertain or perhaps harmful effect As a consequence of this uncertain therapy the physician might be responsible for damages which could endanger his patient s life

We consider it unnecessary to recall the numerous methods and drugs recommended in the past Of those most commonly used we shall discuss briefly the treatment by vaccines which are given with the idea of increasing the immunologic defenses of the patient Experience shows the uncertainty of the results in the acute phase of brucellosis In the chronic phase it seems to us unreasonable to add to the already hyperimmune condition an increase in stimulation The administration of hyperimmune serum or whole blood has not been of value in our cases of acute or of chronic brucellosis

Chemotherapy has recently again been brought to the attention of clinicians this time based on extensive experimental work in which such drugs have shown their usefulness against Brucella Streptomycin and sulfadiazine are credited with being the most useful * Experimental work by Spink and collaborators (1948) however showed that either drug used separately has considerably less antibrucella effect if administered into infected developing chick embryos than if both drugs are administered simultaneously Application of this combined treatment to human brucellosis was made by Eisele and McCullough (1947) and by Spink et al with most encouraging results Spink et al recommended the administration of 0 5 Gm of streptomycin every 6 hours for 2 weeks and simultaneously an initial dose of 4 Gm of sulfadiazine and 1 Gm every 4 hours thereafter The sulfadiazine should be continued for longer periods This method of treatment is now on trial (1948) one must await the accumulation of sufficient data before definite conclusions can be drawn

In this respect we must keep in mind that brucellosis is often a relatively mild disease which may be of short duration with early disappearance of the infecting agent from the blood stream and that in the chronic phase of the disease the usefulness of the antibrucella agents may be of little or no value

In brucellosis one may expect that the acute phase will be followed by temporary remission and later by recurrences usually characterized by *hypersensitivity to Brucella products* For this reason we have followed for the past eight years the plan of desensitizing the patients so as to reduce to a minimum any disturbances caused principally by temperature elevations For this purpose we have used extracts obtained from Brucella very active as allergens but insufficient as stimulants for increased antibody production These extracts are the same as those used for the determination of skin sensitivity and are administered subcutaneously in 2 weekly doses beginning with 1 skin test dose and gradually increasing to 20 doses As may be expected this treatment has little or no effect on the acute phase of the disease but in most cases it may be instituted as early as possible with the hope that at the termination of the acute stage the patient may be in a better condition

*Recently aureomycin and Chloromycetin have been recommended.

judgment must be reserved until completion of those bacteriologic studies covering isolation of the organism from the blood from focal lesions or from bile urine, feces etc

Various media may be used in the isolation of Brucella from the blood but we find Bacto tryptose used in broth and agar practical * Experience has *shown the considerable difficulties in obtaining cultures from the blood of* patients and the danger of handling the material in the process of isolation and identification of Brucella In order to obviate these difficulties we have recommended (Castañeda and Guerrere 1946) the use of a double medium which has proved very valuable

Tryptose agar in amounts of 20 cc is distributed in 100 cc flat sided bottles and autoclaved The medium is allowed to solidify in one of the narrow sides of the bottle With sterile precautions 15 cc of sterile Bacto tryptose dissolved in 2 per cent sodium citrate are added The bottle is closed with an adequate rubber stopper and incubated for several days as a test for sterility Carbon dioxide may be added before or after setting the stopper

The blood is taken as usual by means of autoclaved syringes and ejected through the rubber stopper in amounts of 10 cc At 48 hour intervals the broth and blood mixture is spread over the agar layer the bottle immediately replaced in its vertical position and incubated at 36° C If the blood culture is positive colonies of Brucella may be observed in the agar layer after the fourth day but most frequently after the sixth day If no colonies are observed after 20 days of incubation the culture is considered negative

*Identification of Brucella is rapidly made by determination of the atmospheric re*quirements of the isolated organism by the production of H_2S and by the type of agglutinogen which predominates in the antigenic constituents of the organism In our laboratory we determine the type of agglutinogen by the use of selective agglutination this has given satisfactory results Recourse may be had however to the absorption of the agglutinins or to agglutination by monovalent sera recommended by Evans (1937) *and by Wilson and Miles (193- In a well equipped laboratory determination of the* type of newly isolated strains can be carried out with bacteriostatic media recommended by Huddleson (1934)

The possibility of infection by rough variants of Brucella must not be overlooked In such cases special studies too complicated to be included in this chapter may be required

Treatment

Data on the pathogenesis of brucellosis are meager yet they are worthy of consideration as a basis for treatment There can be no doubt that the possibility of development of Brucella within various types of cells—a more active development than is supposed—constitutes a serious obstacle to successful therapeutic attack Because of its intracellular position the Brucella persists in spite of the high immunity attained by the tissues This persistence explains the allergic character of the principal manifestations of brucellosis

Most methods recommended for the treatment of brucellosis are not efficacious so that we have maintained an attitude of prudent *vigilance, avail*ing ourselves of the natural defenses of the individual and avoiding using

†Difco Laboratories Detroit Mich

depend upon widely varied circumstances. We shall give data only on one relatively frequent complication which requires special treatment.

In the gluteal region at the level of the sacroiliac joint there is often present a myalgia of such intensity as to prevent the patient from moving. The psychic effect of the myalgia is such that fear of pain on movement keeps him in bed for weeks or even months. Contractures and muscular atrophy complicate this condition. Carrillo (1944) described the technic followed in our clinic for the treatment of this complication. Five to 10 c c of procaine are injected into the painful site at a convenient depth. When the trouble is not articular the patient experiences immediate relief. When he discovers that he can move without excessive pain he acquires confidence, his appetite improves and his mental state changes. The treatment is repeated 3 to 4 times at 48 hour intervals. Usually the patient recovers his ability to move within a few days.

One of the most dangerous complications is that which results from hypersplenism leading to severe hemolytic anemia, agranulocytosis or thrombocytopenic purpura. Splenectomy may be required in such circumstances.

to tolerate the constant discharge of products of Brucella which are accompanied by the symptoms described above

Frequently particularly when no important localizations of Brucella are present even though bacteremia continues for weeks and even months after termination of the acute phase patients submitted to the desensitization treatment present a minimum symptomatic picture Many patients have returned weeks and even months later complaining of reappearance of symptoms Renewal of desensitization improves their symptoms which gradually subside

Because of the allergic nature of most of the symptomatology in chronic brucellosis treatment by desensitization has given more consistent beneficial results On the other hand this method is of no value in anergic patients anergy frequently is found in severe and persistent bacteremia related to considerable multiplication of the organisms in the spleen liver endocardium and other important foci of Brucella

Since the treatment by desensitization causes little or no trouble to the patients it may be continued for several weeks or months As a general rule we advise continuance of treatment until the agglutination titers become lower than 1 200 checking the immunologic picture of each patient periodically

In spite of the enthusiasm over successful results by recent therapeutic methods in brucellosis we consider that the solution is far from favorable because of the complexity of the mechanism of brucellary action namely the peculiar intracellular position of the organism and the concomitant phenomena of bacterial allergy It is hoped that further knowledge of antibiotic action may help in the solution of these problems

COMPLEMENTARY THERAPY

Complications of brucellosis such as abscesses arthritis and ascites may be benefited by direct injection of sulfathiazole associated with urea Penicillin has been used successfully whenever complications due to bacterial sensitivity to that drug occur The consequences of neutropenia in brucellosis are appreciable as seen by the facility with which ordinarily insignificant local infections become severe enough to warrant surgical handling We find it necessary to extract all infected teeth remove infected tonsils and even to resort to resection of the gall bladder after confirmation of persistent infection whether brucellary or from another cause As long as a secondary abscess persists there is always the possibility that the pathogenic bacteria or saprophytes may provoke serious complications such as spondylitis myositis suppurated arthritis and osteomyelitis

In addition to changes in the white count many patients show a reduced number of red cells requiring blood transfusion in certain cases occasionally we have administered liver extract and ferrous salts to anemic patients We have administered vitamins preferably thiamin especially in cases with high and persistent fevers calcium salts have been given when needed We cannot include in this chapter those aspects of symptomatic treatment which

CHAPTER 26

TULAREMIA

LEE FOSHAY

Tularemia is an infectious disease of an extraordinarily large number of natural hosts, readily transmissible to man Although its greatest prevalence is in the North Temperate Zone, Tovar (1944) verified its existence within the tropics, and it is likely that further search will enlarge its present geographic range

CAUSATIVE AGENT

Bacterium tularense is a gram negative, nonmotile, unencapsulated, highly polymorphous microorganism with obligate requirements for cystine The morphologic units described by Hesselbrock and Foshay (1945), ranging from 3 μ to less than 0 3 micron, and comprising globi, globules, bacillary forms, delicate filaments, and minute, filtrable minimal reproductive units, were confirmed by the electron micrographic study of Eigelsbach, Chambers, and Cornell (1946), who measured minute units as small as 90 to 110 millimicrons Although it exhibits serologic relationships with Brucella, *Bact tularense* is biologically unrelated to the Brucella *or the Pasteurella, but is more closely related to certain members of the Borrelomycetaceae*

VECTORS AND NATURAL HOSTS

The chief mammalian natural hosts are rabbits and hares, all rodents, many carnivores some marsupials and insectivores, and a few artiodactyls, the rabbits and hares being the chief transmitters to man Among arthropods the chief hosts and vectors are many ticks, flies, fleas, lice, and mites, with ticks of the genus Dermacentor and flies of the genus *Chrysops being the chief vectors to man The chief avian hosts and* occasional vectors to man, are quail, pheasant, grouse, chicken hawk, and horned owl Other hosts responsible for rare infections of man, and possibly for maintenance of contamination of natural waters are certain fish, crustacea, snakes, frogs, and turtles An extensive list of *vertebrate hosts* was recently published by Burroughs, Holdenried, Longanecker, and Meyer (1945) Ticks of the genera Haemaphysalis and Dermacentor are chiefly responsible for maintenance of the reservoir of infection among vertebrates Since these ticks transmit the infection trans ovarially to succeeding generations, they are both reservoir hosts and vectors Man to man *transmission is rare Most human infections follow contact* with infected animals, principally rabbits and hares, or the bites of infected ticks or flies The proof of infectiousness of extensive natural waters by Karpoff and Antonoff (1936) in Russia, by Huseyin (1937) and Öz (1938) in Turkey, and by Jellison (1942) and Parker (1943) and *their associates* in north western United States prompts continued search for water borne infections

PATHOLOGY

The organs most frequently affected are the skin and conjunctivae regional and remotely located lymph nodes, lungs, spleen, liver, and the large serous membranes The fundamental lesion is necrosis at first coagulative, later often liquefactive The surfaces and cut sections of organs usually show few to numerous grayish white focal necroses Liquefaction necrosis

cavities A characteristic feature is the development of a primary lesion and rapid enlargement of regional lymph nodes *without intervening lymphangitis* Regional nodes always enlarge first Further lymphatic extension may engender remote bubo formation even in contralateral nodes without corresponding primary lesions Small multiple dermal lymphangitic nodules resembling those of sporotrichosis appear on the hands and arms in about 7 per cent of cases

Fever is always present usually to 39° or 40° C (102 2° to 104° F) There is often an initial rise a remission and a secondary rise to the initial level The initial rise usually lasts from 2 to 5 days the remission from 1 to 3 days and the secondary rise from 1 to 2 weeks followed by a gradual decline to normal In the absence of regional localizations the febrile period usually lasts from 2 to 4 weeks If pneumonia is present high fever may persist for 4 to 6 weeks Fever may accompany repeated suppuration of buboes or *persisting infection in serous cavities for weeks and even for months* The fever is typically daily remittent with wide fluctuations but in the severest forms it becomes nonremittent at a high level

Cough is a frequent early symptom usually accompanied by bronchitic rales *Unless pneumonia develops it usually disappears before the third week*

Although the studies by Blackford (1935a 1935b 1941) and his associates showed that about 90 per cent of patients develop roentgenologic evidence of bronchopulmonic changes the pneumonia frequency is about 18 per cent hence the majority of early bronchopulmonic lesions do not develop into pneumonic areas Bronchopneumonia may occur in any lobe may be solitary or multiple and with or without pleurisy that may be dry or with effusion but most develop from the hilar regions By extension or confluence they may present the physical signs of lobar pneumonia Bronchopneumonia is an inconstant but an integral part of the general disease primarily hematogenous in origin Early consolidations frequently fail to produce clinical signs

The high frequency of pneumonia in the typhoidal type has suggested the possibility of a primary pneumonic type in which initial infection occurs by inhalation Stuart and Pullen s (1945) review favors this view *but the summarized evidence is unconvincing The existence of a bacteremia* during the initial phase first demonstrated by Francis (1927) has been repeatedly verified by animal inoculations and cultures of blood and indirectly by *most pathologic findings as* Foshay (1937) observed Although some laboratory workers acquired tularemic pneumonia after infected animals sneezed or coughed into their faces others who were similarly exposed and infected did not develop pneumonia The presence of *Bact tularense* in the sputum of patients with pneumonia has been confirmed frequently but not one human infection ascribable to this source has been recorded although many *hundreds of* nonimmunes have been subjected to this kind of exposure The experience of the author with a considerable number of scientific workers who were exposed to infected aerosols or dust clouds containing strains of maximal virulence was *that although a number acquired* tularemia the incidence of tularemic pneumonia was notably lower than that usually observed in the bubonic clinical

is frequent in lymph nodes The lungs may be normal or may show solitary or few large discrete nodules numerous miliary focal necroses, or solitary, multiple or confluent areas of bronchopneumonia or combinations of these lesions Pneumonias may be caused by mixed infections The heart seldom shows gross lesions Pericarditis pleuritis and peritonitis occur usually with effusion Thrombophlebitis enteritis meningitis and encephalitis have been observed also stomatitis mastitis and focal lesions in the kidneys and supra renal glands

Microscopic lesions soon exhibit subacuteness or chronicity Early lesions show chiefly necrosis of tissues and exudates often with extensive karyorrhexis older lesions become granulomatous with little or no necrosis The fundamental cellular reaction is reticuloendothelial monocyte epithelioid The exudate of uncomplicated tularemic pneumonia is typically mononuclear and may be composed entirely of macrophages The comprehensive monograph by Lillie Francis and Parker (1937) should be consulted for detailed studies

CLINICAL SYMPTOMS

The distinguishing features of the four clinical types described by Francis (1927) and the type frequencies determined by the writer for 1 443 cases are as follows

Ulceroglandular with primary lesions and regional buboes This is the commonest type with a frequency of 84 per cent

Oculoglandular with conjunctival primary lesions and regional buboes The type frequency was 4 per cent

Glandular, with buboes but without any primary lesion The type frequency was 2 per cent

Typhoidal with neither primary lesions nor buboes The type frequency was 10 per cent This type differs notably in that its pneumonia frequency is three times greater and its fatality rate is four times greater than those of the combined bubonic types

The incubation period is usually from 2 to 5 days but may vary from less than 24 hours to 13 days Prodromal symptoms are rare The onset is characteristically sudden with chills or chilly sensations fever sweats aching bodily pains and sometimes nausea and vomiting Colicky abdominal pain and diarrhea may occur at the onset Headache and mental dullness occur frequently Severe infections usually produce delirium stupor and a semi comatose state

Subsequent to the abrupt prostrating onset most patients develop chancre-like primary lesions and regional buboes Primary lesions usually develop at contaminated areas before buboes become apparent Either is usually apparent within 2 days after onset and either or both may be present at the onset Primary lesions begin as painful necrotizing papules which enlarge ulcerate and become indolent ulcers with raised edges vertical walls and ragged necrotic floors Most occur on the fingers hands or arms but they may arise on the skin elsewhere or on the mucosa of the oral, nasal, and pharyngeal

Serum Agglutination Test—The macroscopic agglutination test is the standard and preferred procedure Slide tests to demonstrate serum agglutinins may be used as presumptive tests but they are inadequate to resolve the commonest diagnostic difficulties which require estimation of titers

Serum agglutinins never appear before the eighth day of disease they usually appear during the second week and rise rapidly to high titers in the third week Infrequently their appearance may be delayed until the third week and rarely until the fourth week Third week titers are seldom below 1 640 All patients develop agglutinins unless death occurs prior to the end of the second week and even then most will reveal postmortem titers Agglutinins acquired by infection usually persist for the life of the patient the titer falling gradually Ascending titers from zero during the first week to high levels during the third or fourth weeks are wholly convincing Titers that remain at about the same moderate level in the absence of characteristic clinical findings occur typically in recovered immune individuals Ransmeier and Ewing (1941) recently presented a critique of the agglutination test

Reciprocal cross agglutination with *Brucella* may occur especially whenever the homologous titer is high Since the homologous titer is almost always the higher one cross agglutination seldom causes diagnostic difficulties This is also true for the much less frequently observed falsely positive Weil Felix reaction Since agglutinins usually persist for many years this test can never be used to indicate recovery

Intradermal Tests—Intracutaneous injection of 0 05 c c of a dilute formalin killed suspension the test dose containing about 6 000 cells provokes a specific papulo erythematous reaction after 48 hours Positive reactions occur in about 93 per cent of cases early in the disease before serum agglutinins appear Intradermal tests may stimulate agglutinin formation as noted by Friedewald and Hunt (1939) but the inconstant and low titers so produced are easily distinguishable from agglutinin curves caused by infection Immune persons usually give positive reactions for many years after recovery

Cultures—Cultures of blood or exudates on glucose or glycerol cystine blood agar are sometimes successful Isolation is more reliable after inoculation of source materials into mice or guinea pigs followed by heart blood or splenic pulp cultures at time of animal death The danger of self infection from handling infected animals is great it is less but still significant from handling virulent cultures

Smears—It is useless to attempt confirmation by examination of stained smears since it is practically impossible to distinguish bacteria from minute karyorrhectic fragments or other granules

Blood Counts—There are no characteristic blood findings Leucocytes vary from 5 000 to 20 000 per cubic millimeter with usually a polynucleosis but the counts have no diagnostic value A mild to moderate degree of secondary anemia is an inconstant finding

types Tularemia has not yet exhibited a primary pulmonic type, with air-borne transmission from person to person, analogous to the pneumonic form of plague

A variable and nonpathognomonic exanthem occurs in about 20 per cent of cases, usually during the second or third week The various eruptions are described and illustrated by Hitch and Smith (1938) Typical erythema nodosum occurs infrequently

Weakness, loss of weight, recurring chills, sweats and sensation of prostration are characteristic of the acute phase After the fourth week profound fatigue is often the outstanding complaint The gravest **prognostic sign** is the association of constant delirium or stupor with a nonremittent high fever, often but not always indicative of the onset of septicemia Additional findings confirmatory of septicemia are progressive enlargements of the liver and spleen, deepening jaundice, progressing involvements of the lungs brain, and meninges, with deepening coma

The duration of disease varies from 2 weeks to 15 months or longer, but is usually about 4 months The most frequent causes of prolonged illness are successively suppurating buboes persisting or migratory pneumonic lesions and their sequelae, and persisting infection of the pleural or peritoneal cavities Suppurative adenitis occurs in more than half of all cases with buboes, usually during the second month and thereafter Buboes that have disappeared may suddenly reappear as late as 2 or 3 years after apparently complete recovery Many of these liquefy rapidly

Cases that are mild throughout the entire course are seldom seen, but in many the symptoms that recur with the secondary rise in temperature are milder than those of the usually stormy onset These patients may be bedridden for only a few days and become ambulatory soon thereafter

The **prognosis** for survival is good in the absence of pneumonia less favorable if pneumonia is present and grave if septicemia supervenes Patients with pre-existing coronary or rheumatic heart disease are notably poor risks Most deaths occur between the eleventh and eighteenth days of disease, usually from septicemia, less frequently from severe intoxication or heart failure The case fatality rate is about 6 or 7 per cent

Relapses or recrudescences occur infrequently from 8 months to 2 years after onset Although usually solitary and of short duration, infrequent examples of repeated relapses throughout 1 to 2 years have been observed

Recovery from attack confers a permanent immunity Inapparent or subclinical tularemia is rare, and apparently limited to scientists who have either handled strains of low virulence or who have been protected by prophylactic vaccination Francis (1936) noted that repeated exposures may induce trivial local reinfections in recovered persons

LABORATORY DIAGNOSIS

Although 90 per cent of human tularemia representing the bubonic types, can usually be diagnosed from epidemiologic and clinical findings the deceptive typhoidal type often presents great difficulties Laboratory tests, if properly applied and interpreted, give extremely reliable confirmation

monary serosal or other regional localizations should be treated to avoid serious sequelae and to prevent the establishment of prolonged illness and disability

Patients who have weathered the severe phase and who have reached the fourth week of disease without pneumonia or other visceral lesions with little or no fever and without evidence of progressive bubo formation will seldom need special treatment

Ocular lesions are best treated locally with continuous wet dressings of warm magnesium sulfate saline solution with frequent lavage of the con junctival sac with warm boric acid saline solution

Primary lesions should not be incised unless secondary pyogenic infec tion requires drainage Dressings wet with saturated solution of magnesium sulfate are sufficient Suppurating buboes require drainage as soon as the nodes become liquefied

PROPHYLAXIS

Prophylactic studies by Foshay (1942) and associates indicate that prophylactic vaccination prevents many infections and markedly ameliorates the disease if it is acquired subsequently Until better vaccines become avail able personal prophylaxis must depend upon avoidance of sources of infec tion the use of rubber gloves to handle infected animals or carcasses and the removal of ticks before attachment occurs Whenever the disease is fly borne personal prophylaxis is difficult The chlorination studies of Foote (1943) and associates indicate that standard chlorination procedures should give effective community prophylaxis against water borne tularemia

TREATMENT

General Management—Complete rest in bed is necessary during the initial phase when fever is high prostration is severe and drenching sweats are frequent Since man to man transmission is extremely rare strict isolation of the patient is unnecessary Rubber gloves should be worn to dress ulcerated primary lesions to incise and dress suppurating buboes and to perform paracenteses Otherwise there is no need for precautionary measures beyond ordinary care and cleanliness on the part of sickroom attendants

The diet should be liquid during the severe phase high in carbohydrate and fruit juices semisolid to light as the fever declines with resumption of full diet as soon as appetite returns Chair privilege and ambulatory status may be granted as soon as temperature and pulse rate are normal and as strength returns

Specific Therapy—Serum therapy according to reports by Foshay (1940 1946) induces significant lowering of mortality and highly significant reductions in morbidity Although effective in terminating prolonged illness not in excess of 10 months the most significant favorable effects follow treatment before the end of the second week of disease and especially in patients with the typhoidal clinical type

In the absence of pneumonia 30 c c of the serum administered intravenously or intramuscularly is usually sufficient If pneumonia is present the initial dose should be 60 c c and more may be necessary Reduction in fever and re establishment of mental clarity are the best guides for quantity frequency and duration of treatment

Chemotherapy—Streptomycin is a valuable and effective therapeutic agent Early reports by Foshay and Pasternack (1946) Abel (1946) Foshay (1946) and Howe Coriell Bookwalter and Ellingson (1946) indicate that it induces prompt and highly significant reductions in morbidity that it is more effective than serum therapy for the desperately ill patient but that streptomycin like serum may exert little effect in the late stages of prolonged illnesses

A total dosage of 2 Gm of streptomycin base is sufficient This may be given after solution in physiologic saline either by intramuscular injection every 3 hours or by continuous hypodermoclysis at a rate of 0 25 Gm every 12 hours for 2 days followed by 0 25 Gm daily for 4 additional days

Penicillin is ineffective* No sulfonamide nor any other drug has been *demonstrated to modify significantly the natural course of the disease*

Indications for Therapy—Early treatment during the severe initial phase will effect the greatest shortening of disease and the lowest mortality The presence of pneumonia pleurisy peritonitis or other visceral lesions are indications for prompt treatment The intervention of sustained high fever associated with delirium and stupor is an urgent indication Continued disease into or beyond the second month usually caused by lymphatic pul

*Editor's note (O F) Recently aureomycin Chloromycetin Neomycin, and terramycin have been recommended

CHAPTER 27

PLAGUE

ATILIO MACCHIAVELLO

(TRANSLATED BY ANTHONY DONOVAN)

GENERAL DESCRIPTION

Plague is an acute, febrile, transmissible disease, infectious and contagious, the specific etiologic agent of which is *Pasteurella pestis* It is essentially a zoonosis of rodents, and under certain circumstances it is transmitted to man, usually by the bites of fleas infected from rodents in the septicemic phase of acute plague The fleas abandon their natural hosts when these die of the infection, and seek blood meals on secondary hosts, one of which may be man

In exceptional circumstances, secondary pulmonary localizations may *occur in bubonic or septicemic plague, and may give rise to air borne contagion* from man to man, thus provoking cases of primary plague pneumonia without the involvement of rodents or fleas in the transmission cycle

Human plague (oriental plague, or plague "of the Orient," the "Black Death," or simply "the plague") continues to be one of the most important problems of tropical medicine On the American continent the disease manifests certain specific characteristics which will be emphasized in the course of the descriptions below

HISTORY

It is not possible to state with exactitude the first time that plague occurred among mankind although there are documents as ancient as the Bible (I Samuel, Chapters 5 and 6) wherein the disease is mentioned as "tumors in the secret parts" Dionysius the Hunchback, Dioscorides (first century A.D), Poseidonius (150 135 B C), Rufus of Ephesus (*circa* 100 A D), and Oribase (325 400 A D) among others, described or cited data referring to plague, especially in Libya Egypt, and Syria The epidemics known as the plague of Athens, described by Thucydides (430 B C), the Antonine plague, and the plague of Carthage all antedating the Christian era, possibly were not plague However, the great pandemic which began in 542 A D , generally called the plague of Justinian—*glandularia* or *pestis inguinaria*—was undoubtedly plague, [illegible] Italy, Gaul, Germany, and has been descrit [illegible] s of Caesarea in Constantinople, and by [illegible] mic manifestations it receded from Europe and Asia Minor, having wiped out half the population of the Roman Empire

In the fourteenth century, from 1346 to 1353, there occurred the most terrible of all pandemics of plague Beginning in Asia Minor it advanced to eastern Europe where it took a toll of 13 million victims (Hecker, 1832) It then extended along the Mediterranean Sea, and progressively invaded all the countries of Europe except *the arctic zones* of Greenland and Iceland, with death of a quarter of the population of the continent Pope

ETIOLOGIC AGENT

Pasteurella pestis, discovered by Yersin in 1894, is a member of the group causing hemorrhagic septicemias Taxonomically it belongs to the genus Pasteurella, and may be characterized as a heterotrophic microorganism, 1 to 2 microns long a coccobacillus but with accentuated pleomorphism, nonmotile, nonspore forming, rarely capsulated, often showing a pseudo capsule or envelope (Rowland, 1914), aerobic and a facultative anaerobe, easily stained with the aniline dyes, with a characteristic bipolar staining gram negative Under favorable conditions the morphology is variable, giving rise to the so called involution forms It grows easily on ordinary media It does not liquefy gelatin broth is

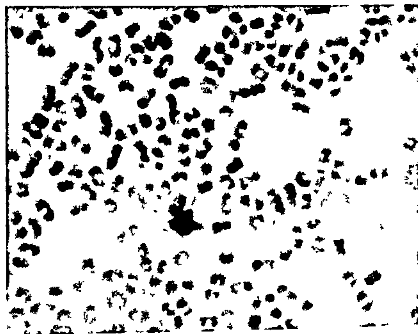

Fig 148—*Pasteurella pestis* (×3 000 approx)

not made turbid, but a film is formed, with stalactite formations (Haffkine), which break on the slightest movement Milk is not coagulated, nor is litmus milk altered or at the most a slight acidity develops On solid media the colonies appear like dewdrops in 48 hours, and soon form a basal extension on which secondary colonies grow Usually only rough colonies are described whether virulent or not, but some authors also describe smooth colonies (Pirie, 1927, Rachinski, 1930, Otten, 1934, Pokrovskaya 1934, Macchiavello, 1941) Excessive envelope formation causes a viscous growth Indol and H_2S formation, and Voges Proskauer test are negative Rhamnose and glycerine are occasionally fermented, the latter only by certain strains called "glycerine postive" or "alpha" by Kurauchi (1930), and "continental" by Berlin and Borzenkov (1940), in contrast with the other "glycerine negative" "beta," or "oceanic" strains Optimum temperature is between 25° and 30° C Growth takes place between 0° and 43° C.

Past pestis constitutes a single serologic group Different strains vary in virulence, morphology, colony structure etc It has slight resistance to the effects of external

Clement VI estimated the total number of deaths caused by the Black Death to have been 42,836,486 Pneumonic plague was mentioned for the first time (Guy de Chauliac, 1363, and others), as well as quarantine measures which were initiated in Reggio, in 1374, and in Venice, in 1422, and were adopted by other countries

Between the fifteenth and eighteenth centuries epidemic outbreaks of plague continued, notably those of Milan, 1630, London, 1665, in which year 60,000 of the 450,000 inhabitants of the English capital died of the disease, Marseilles, 1720, where the epidemic was so intense as to cause a thousand deaths daily, and a total of 40,000, Messina, 1743, where 43 000 perished, and Russia, 1770, with a mortality of 80,000 In the nineteenth century, plague retreated toward the Orient, and in passing caused the epidemics of Constantinople in 1803 and 1813, with final outbreaks in Benghazi, Tripoli, in 1858, and in Russia, 1878 1879

The disease was now thought to have been dislodged definitely from Europe when in 1894, the city of Canton was invaded by the infection from Chinese Yunnan In 1896 plague appeared in Bombay, transported from Hong Kong or Pakhoi, or, according to Hirsch directly from Guhrwal and Kumaun Rapidly the epidemic extended to various points in India* by land and water routes, and soon to the entire world, obtaining a foothold in South America in 1899, and in North America one year later

Curiously enough, plague entered South America by the inland river port of Asuncion, Paraguay, in April, 1899 (Agote and Medina, 1901) From here the infection was transmitted to the Argentine ports of Rosario, Formosa, Corrientes, and Buenos Aires (September, 1899, to January, 1900) The second incursion of plague on the continent was at Santos, Brazil, in 1899 (Andrade, 1899) and the third at Montevideo, Uruguay, in 1900 (Fernandez Espiro, 1916)

On the west coast of South America, plague first occurred in 1903, at Callao, Peru (Artola 1903) and soon after in Iquique, Chile (Macchiavello 1932) In 1904, Antofagasta, Chile was infected directly from India by means of a shipment of jute sacks (Ferrer, 1905) In 1908 the chief plague episode in South America began in Guayaquil, Ecuador (Suárez, 1927) From there the infection jumped to LaGuayra, Venezuela (Acosta and Razetti, 1909) Bolivia was infected much later in 1921 1922 but the source of the infection is not clear (Veintemillas 1936)

In the United States the disease was reported in San Francisco on March 6, 1900 (Kinyoun, 1901) Soon murine plague spread inland and gave rise to the disease in wild rodents, and this type of infection, suspected by Blue in 1903 and confirmed by Wherry (1908), has been maintained and has been spreading eastward up to the present time

Cases of plague were reported from Mexico, in 1902, at Ensenada de Todos los Santos and Mazatlán (Liceága 1903) With the exception of Haiti, Colombia, and Central America (but including British Honduras and Panama), all of the countries of the American continent have suffered plague infection to a greater or lesser extent (Moll and O'Leary, 1940 1942)

GEOGRAPHIC DISTRIBUTION

Nearly every important country of the world was invaded during the course of the last pandemic which originated in Yunnan, China At present the principal endemic foci of plague in rodents are murine—India, China, Manchuria, Mongolia, Burma, Dutch East

*It was during this epidemic that the most notable contributions to the knowledge of plague were made by Kitasato (1894) Yersin (1894) Hankin and Leumann (1897), Childe

rat burrows Physical conditions favorable to plague may be nautical (ports) urban rural or sylvatic the first three with relation to domestic rats the rural conditions with relation to wild rodents which although living separate from human habitations share with rural man the areas cultivated by him or his agricultural or field dwelling neighbors the sylvatic totally independent of man this explaining the rarity of human plague of sylvatic origin

Social conditions influence the development of plague through population density congestion and use of buildings the facilities existing for the renewal maintenance and increase in rodent populations etc

Fig 149 —*Xenopsylla cheopis* in act of copulation

External climatic conditions the *macroclimate* define the geographic limits of plague principally through the effects of humidity and temperature on fleas The incidence of the disease is also influenced by the mechanical action of torrential rains on rats and fleas when they are dislodged from burrows (Eskey 1934) Climate also influences incidence of this disease through the effects of cold and possibly through atmospheric oxygen tension by effecting the development of the pneumonic forms Temperature and humidity govern the developmental cycle of the flea including procreation evolution from egg to adult and longevity they affect the relationship between fleas and hosts the periodicity and frequency of the infection the duration of extrinsic incubation the duration of the proventricular blockage in plague infected fleas the hibernation of fleas and their survival time away from their hosts they influence moreover the initiation duration and decline of the so called plague seasons " which vary from one locality to

agents such as sunlight and desiccation except when protected by organic substances It deteriorates rapidly under tropical conditions (Macchiavello and Paracompos 1941), it maintains its viability and virulence in the cold (Kasanski 1898 Francis 1943) Experimentally it produces typical disease in laboratory rodents differentiation is aided by its property of penetrating intact or slightly abraded skin and mucous membranes (Albrecht and Ghon 1898 1900)

EPIDEMIOLOGY

Apart from the etiologic agent the epidemiology of plague is influenced by the hosts and vectors of the infection by the surrounding conditions and by the sources and means of contagion and spread of the disease

Hosts

Plague is primarily a disease of rodents these rodents acting as hosts Taxonomically they belong to the families Muridae (rats and mice) Sciuridae (squirrels and marmots) Leporidae (hares and rabbits) Jaculidae (gerbilles) and Cavididae (guinea pigs) Ecologically rodents may be classified as domestic especially those of the subfamily Murinae genus Mus and Rattus wild those most closely related to plague being Sciuridae of the genera Citellus and Marmota and hibernating rodents the more important of these being the tarabagan (*Arctomys bobac*) of Mongolia and Transbaikalia the suslik (*Citellus citellus*) of Russia the gerbille (*Taterona lobengulae*) of South Africa and the ground squirrel (*Citellus beecheyi*) of the United States In Asia the Sciuridae are the ancestral reservoirs of plague in Africa and America these have been infected by domestic rodents Among the latter those most actively involved in plague are rats especially *Rattus norvegicus (Mus decumanus) Rattus rattus rattus* and *R r alexandrinus* which are differentiated by their habits (sewer rats roof rats and palm rats respectively) and appearance Plague is infrequent in animals other than rodents There is mention of its occurrence in monkeys Insectivora Carnivora (especially cats ferrets and the mongoose), in camels d delphis etc

Vectors

The principal vector of plague infection and practically the only one is the flea (Ogata 1897 Simond 1898 Gauthier and Raybaud 1903) an arthropod of the class Insecta order Siphonaptera the principal ones being Pulicidae subfamily Pulicinae with the genera Ctenocephalides Hoplopsyllus Juxtapulex Pulex and Xenopsylla (fleas of the dog and cat of squirrels of pigs of man and of rats respectively) Dolichopsyllidae subfamilies Ctenophthalminae (genus Ctenophthalmus) and Dolichopsyllinae (genera Ceratophyllus Diamanus Nosopsyllus Oropsylla Orchopeas Opisodasys Opisocrostis, and Thrassis) the genus Nosopsyllus (*fasciatus londiniensis* etc) being fleas of rats in cold or temperate climates and the others principally infesting sylvatic rodents marmots squirrels and others Malacopsyllidae of the genus Rhopallopsyllus which includes the fleas of domestic and wild guinea pigs Tungidae principally the genus *Echidnophaga (E gallinacea the chicken flea)* and *Hystrichopsyllidae among which the* Leptopsyllinae *L musculi (segnis)* the domestic mouse flea is of interest to us Besides the fleas of wild rodents the fleas which are important in the transmission of plague are the Nosopsylla in temperate climates and in hot climates the Xenopsylla especially *X cheopis* and secondarily *X astia* and *X brasiliensis*

Ecologic Conditions

Ecology plays a preponderating role in the development maintenance extension and decline of plague with regard to surrounding physical conditions social conditions the external macroclimate or the microclimate of the

duced by the bite Climatic conditions which regulate pulicine biology are important in defining the plague season Carrying over of the infection from one plague season to another depends largely upon whether the epidemic is complete or incomplete (Gill, 1928, Browning Smith 1912, Kunhardt, 1912, Strickland 1933), for repetition of the disease is more apt to occur when a number of susceptible rats have survived among the murine population

A plague epizootic in a locality may not be accompanied by epidemic manifestations but these generally occur in variable grades depending largely upon the species of rats and fleas present When *R norvegicus* co exists with *R rattus* there is first an epizootic among the Norwegian rats, then among the latter rodents and, later, human infection (Indian Plague Research Commission) In hot, tropical climates and in cold climates an epizootic may remain completely subterranean, without producing a single human case, the epizootic being favored by the favorable microclimate of the nests

When an epizootic is complete, that is to say when it affects all the rodents of a locality, it tends to disappear in a single plague season When it is incomplete, it tends to perpetuate itself year after year Perhaps the role of the fleas is important in maintaining interseasonal plague in certain countries as has already been stated

Rats play an important role in the transportation of plague to distant parts ("metastasis"), but perhaps fleas are even more important than rats In the Western Hemisphere, infection along the coast of the South Pacific (Chile and Peru) was transmitted through bales of jute bags from India carrying infected fleas This was suspected by Long and Mostajo 1934 and proved by Macchiavello 1945 Human epidemics are conditioned entirely by the variables rats, fleas, and climate, to which must be added the degree of contact which rats have with men and the density of the human population From the practical point of view every human case of plague should be considered as terminal except cases of plague pneumonia The intervention of *Pulex irritans* in the transmission of plague from man to man appears unimportant (Petrie and Todd, 1923, Martin, 1913 Macchiavello, 1944), although a few authors consider it relatively important (Wilkinson, 1920, Lethem, 1923, Hirst, 1922, Wu Lien teh, 1926, Eskey, 1930)

Transmission of plague pneumonia occurs by droplet infection as in other respiratory infections Pollitzer (1943) has suggested that the decline in epidemics of primary plague pneumonia is due to the fact that the infection is so grave and the secondary septicemia develops so early that the patients die before they begin to cough and expectorate, thus cutting the chain of contagion

Sylvatic plague is maintained principally by the involvement of its own vectors, which act in part as reservoirs On the other hand the role played by these same animals in maintaining the latent infection during hibernation is also important In Asia and Russia human infection from wild rodents in most cases takes place by direct contact

In only three American countries—the United States Argentina, and Brazil—is there evidence of the extension of plague from domestic to wild rodents, but the definite and independent establishment of the infection in wild rodents has been proved only in the United States The actual situation with regard to sylvatic plague in North America has been reviewed by Meyer (1942) In 1903, Blue suspected the relationship between a fatal case of plague occurring in Contra Costa County, California and squirrels which had died in large numbers between 1903 and 1905, by a plague epizootic proved by Long and Wherry By catching and exterminating squirrels, which was begun by Long Wherry (1908) was able to prove plague infection among them In 1910, under the direction of

another Different species of fleas require different levels of humidity and temperature to transmit plague *X cheopis*, for example transmits the infection most effectively at temperatures between 15° and 26° C, with humidity from 75 to 95 per cent *Nasopsyllus fasciatus* and *N londiniensis* can transmit at lower temperatures, but with decreased activity (Raybaud, 1911, Bacot, 1915, Macchiavello, 1942)

Microclimate refers to the conditions within the rat burrows, which may differ greatly from those of the external air The progressive occurrence among rodents of the completely subterranean and "silent" epizootics is made possible by the influence of the microclimate (Buxton, 1933 Russell 1934 Macchiavello 1941) It also favors the survival of plague infected fleas in rat burrows for long periods of time—up to 8 months for *X cheopis*, according to observations of the author in Peru (1945)

Epidemiologic Mechanism

The sources of plague infection are the blood of infected rodents in the septicemic phase of the disease and the sputum of human plague pneumonia cases, the route of transmission is the pulicine vector or air borne droplets Other materials of human or animal origin also may be infectious—urine, feces, the skins of wild rodents—but this is exceptional Regarding the dissemination of plague, it has been observed that the great pandemics originate in the ancestral foci of the disease whereas epidemics within a country after the first invasion, originate from other more or less recent outbreaks and locally there is generally an annual recurrence *in situ*

It is not known what was the mechanism of plague infection before the Norwegian rat (*R norvegicus*) which reached Europe in 1716 (Jorge 1928), and the black rat (*R rattus*) (invading that continent with the return of the Crusaders in the twelfth century) had attained the preponderance of today (Hinton, 1918)

The role played by rats in the epidemiology of plague is influenced by several factors, such as the period of procreation the density of the murine population the development of immunity or resistance etc, but maintenance of plague by chronic infection, by cannibalism among the rats or by other means is unimportant A better explanation for the perpetuation of the infection is the continuous passage of plague from rat to rat, in violent outbreaks in months climatically favorable for plague (plague season), and in a more attenuated form during the remainder of the year (Russell, 1934) This explanation however is not completely satisfactory nor has it been proved There is an increasing tendency to attribute to fleas the preponderating role in the maintenance of interseasonal plague (Evseeva and Tirsov 1932, Wassilieff, 1933, George and Webster, 1934, Macchiavello, 1945) just as earlier the importance of the flea in the transmission of the disease was proved

Plague of fleas is not always transmissible Blockage of the proventriculus by a plug of *Past pestis* is necessary before the flea can transmit the disease Blockage occurs only after a period of extrinsic incubation of the infection, which is shorter in the *X cheopis*, longer with *N fasciatus*, and also varies with climatic conditions (Bacot and Martin 1914, Eskey and Haas, 1940) A "blocked" flea infects the blood which it has ingested from a healthy individual, in its buccal cavity The blood is regurgitated and thus infects the wound pro-

PATHOLOGY

In laboratory animals the principal signs of experimental plague are necrosis at the point of inoculation; neighboring lymphadenopathy; gelatinous edema and congestion of the subcutaneous tissues, especially around the aforementioned gland enlargement, showing an intense periadenitis; congestion, hemorrhage, or caseation of the gland, necrotic points in the spleen or liver accompanied by hypertrophy and cloudy swelling; rarely necrotic points or areas in the lung; pleural effusion; hypertrophy of the heart, congestion, emboli, or hemorrhages in the serosa, septicemia. In many animals the localization of the buboes in spontaneous plague is different from that in experimental plague, and is due to the site of predilection of the fleas (the neck in

Fig 150—Typical plague lesions of lymph glands and spleen in guinea pig inoculated by abdominal scarification Note also lung lesions, which are seen less frequently

rats) Both chronic plague and the "inapparent" plague mentioned by McCoy (1910), Morales (1921), Bordas et al (1922), Williams and Kemmerer (1923), Long (1932), and Macchiavello (1932) have been found by us in South America, although we are not prepared to define their epidemiologic importance The type called "peste mitigada" by Swellengrebel and Otten (1914) is seen more frequently; this is very similar to that found in rats in certain zones in Peru We have described a special pathology in laboratory animals inoculated with Brazilian strains of *ingua de frio* (ambulatory plague) (1941).

McCoy, plague had been found in 402 of 150 000 squirrels examined (0 26 per cent) Studies by this author and by Meyer and Eddie proved the susceptibility to plague of a series of wild rodents which later were found infected in nature Until 1934 the California ground squirrel *(Citellus beecheyi beecheyi)* was the only rodent recognized as responsible for sylvatic plague By 1942 Meyer and Eskey had extended the list to 31 rodents as follows *Citellus beecheyi douglasii C b fisheri C armatus C beldingi oregonus C columbianus columbianus C c ruficandus C lateralis chrysodeirus C richardsonii elegans C r nevadensis C r richardsonii C variegatus grammurus C v utah C washingtoni loringi C w washingtoni* all of these corresponding to six large and nine small species of ground squirrel red squirrels of the genus Tamiasciurus *T douglasii albolimbatus* flying squirrels of the genus Glaucomys *G sabrinus lascivus* chipmunks of the genus Eutamias *E leucurus cinereus E panamintinus* and the marmots *M flaviventris engelhardti* and *M f nosophora* Together with these Sciuridae the family Cricetidae of native wood rats and wood mice is represented by the genus Neotoma *(N cinerea occidentalis N fuscipes mohavensis N lepida intermedia)* and by the genus Peromyscus *(P truei gilberti P truei truei)* and the family Heteromyidae by the genus Dipodomys *(D ordii ordii* the kangaroo rat The order Lagomorpha (rabbits and hares) is represented by *Sylvilagus nuttallii nuttallii*

By inoculation with an emulsion of fleas obtained from rodents Eskey was able to establish the experimental transmitting capacity of about twenty of the fifty species found on sylvatic rodents Although it is known that *D montanus* and *H anomalus* parasites of *C beecheyi* are capable of transmitting plague very little is known of their bionomics

In 1941 plague infection was known in 12 of the western states of the United States and in the Province of Alberta Canada Of the 504 cases of human plague which occurred in the United States between 1900 and 1944 only about 65 were related to sylvatic plague, nearly all of these in California The true causes of the extension of sylvatic plague into new areas are difficult to determine Infection by contiguity plays a certain role and possibly also the transportation of infected fleas by field mice or by certain predatory birds (Jellison 1939) which are resistant to the disease

In Argentina human plague of sylvatic origin is also rare and it is possible that originally sylvatic or field rodents contracted plague from domestic species Uriarte (1935 1936) Savino (1935) De la Barrera (1936 1939 1940 1942) Pardal (1941) Alvarado (1938) Falla (1941) and others have studied the epidemiology of sylvatic plague calling it at times rural or field plague According to these studies rodents found infected up to the present time are *Graomys griseoflavus griseoflavus Gr gr centralis Hesperomys murillus cordobensis Galea musteloides leucoblephara Microcavia australis M a joannia Lepus europeaus* etc A recent paper of Savino (1944) suggests nevertheless, the concomitance of plague in rats with epizootics in rodents termed peri domestic Further studies are required to establish the independence of sylvatic plague as a primary entity Studies are also lacking on the vector capacity of a large number of new species of fleas collected by De la Barrera and classified by Jordan (1939 and 1942) such as *Hectopsylla gemina H cypha Polygenis platensis cisandinus Tanallus galeanus Dysmicus barrerai D hapalus D ivanus Tiarapsylla argentina T amastus plesius T longinasus Dolostichus octomyos Craneopsylla andricus Ectinorus trionyx E disjugis E polymerus E setosicornis* etc Experimentally sensitivity to plague infection has been proved in a large number of wild rodents although these have not been found spontaneously infected

The author (1941) demonstrated that true sylvatic plague does not exist in Brazil Epizootics which at times are extensive among sylvatic rodents *Galea spixi* rabbits etc, accompany the infection in field rats *Cercomys Oryzomys intermedius* and mice The species *Peramys domesticus* and some *Didelphis* species appear to act as intermediaries between domestic and sylvatic plague episodes The climatic conditions in open fields especially the extreme dryness of the air impede the maintenance of a pulicine fauna in sylvatic animals *X cheopis* in the few months of the year in which the climate is favorable is a temporary parasite of sylvatic rodents being transported by *Galea* and the other animals already mentioned Sylvatic plague has not been described in the other South American countries

the designation *primary* and the later additional clinical pictures as *secondary*—definitions justified by their physiopathologic evolution

Although cutaneous plague and gastrointestinal plague may on occasion appear initially as primary clinical forms intrinsically they are variations of the bubonic or septicemic types The so called cerebral plague plague meningitis chronic plague plague marasmus *pestis minor*, or *minior*, ambulatory plague and *pestis major* should not be considered as independent clinical entities

PRIMARY BUBONIC PLAGUE

Period of Incubation

The period of incubation is from two to five days with a maximum of ten to twelve days In cases of accidental inoculation (Pestana and Levi in Oporto Strickner in Bombay Evans in Calcutta) the period was from two to three days In 26 cases which had had only one exposure to infection the author found an average incubation period of three and a quarter days including the time the flea delayed in biting the individual In India incubation periods of twelve to fifteen hours have been reported

Prodromal Symptoms

In the great majority of cases the disease has an acute onset without premonitory symptoms In cases where the invasion is slow it is difficult to define which symptoms should be catalogued as prodromal especially if the cardinal sign—the bubo—appears late If the chill is considered as the initial symptom the *prodromal symptoms* may on occasion include general weakness anorexia dizziness nausea lumbar pain restlessness and weakness of the extremities The primary cutaneous lesions are at times of great importance

Invasion

Most commonly the invasive period is not only sudden but extremely acute the disease beginning with a single prolonged intense chill or with less severe but repeated chills accompanied by trembling or shaking The initial clinical picture resembles that of any grave infectious disease After the chill there follow fever weakness headache nausea vomiting anxiety retrosternal constriction vague aches backache conjunctival injection vertigo a reeling gait (plague drunkenness) swollen facies furred tongue rapid pulse dyspnea etc At times in a few hours and usually within a day the disease is fully developed

Course

During this period one or more of the following symptoms and physical signs are seen varying in intensity from the complete absence of one or more to the predominance of a group giving a special clinical picture The clinical manifestations vary from one epidemic to another or in the same outbreak and even in the same house the cases are subject to great individual variation The nervous digestive respiratory and lymphatic signs and symptoms are

In human plague the pathologic findings may be summarized as follows

In bubonic plague (1) A vesicle indicating the site of the infective bites is rarely observed (2) congestion hemorrhage and edema of the lymphatic glands especially those which make up the primary bubo surrounded by edema and periglandular infiltration and by a hemorrhagic exudate due to extravasation of blood (3) toxic destruction of the vascular and lymphatic endothelium manifested by blood extravasations and by cutaneous and serosal petechiae (4) congestion of all the organs especially the spleen liver brain meninges and kidneys (5) dilatation of the right heart with fatty degeneration of the cardiac muscle (6) hypertrophy of the spleen

In secondary plague pneumonia the lymphatics of the parenchyma are especially involved while in primary plague pneumonia the process is essentially an alveolitis (Nattan Larrier and Richard 1931) At first the pneumonia is lobular later there is a tendency to lobal involvement There are congestions of the bronchial mucosa and hypertrophy of the bronchial glands there is also congestion of the larynx and trachea An exudate which is hemorrhagic but which contains little fibrin fills the alveoli and bronchioles desquamated cells and enormous numbers of *Past pestis* are found in this exudate In the septicemic form pathologic findings are relatively lacking except for generalized congestion and splenic hypertrophy

A detailed study of the physiopathology of experimental plague infection was made by Macchiavello and Uriguen (1944) in guinea pigs using Ecuadorian strains characterized by their great invasive capacity and slight toxicity These studies may help in understanding the mechanism of the secondary pneumonic localization in bubonic plague Primary plague pneumonia has been intensively studied by Wu Lien teh (1926 1936)

CLINICAL PICTURE

Clinically there are two types of human plague with and without buboes The latter may occur with septicemia or with pulmonary localizations It is for this reason that three clinical forms of plague are usually described bubonic septicemic and pneumonic

The relative frequency of the bubonic type predominates but is variable from one place to another In India 70 per cent of the cases are bubonic and the rest septicemic pneumonic plague being rare In Chile in 1903 of 214 human cases of plague the frequency of type was bubonic 70 6 per cent ambulatory 9 5 per cent septicemic 15 5 per cent pneumonic 4 4 per cent In Brazil in 1939 1940 of 205 cases the proportions for the same types were 71 2 per cent 19 per cent 9 8 per cent and 0 0 per cent In Ecuador Saenz Vera (1939) found that whereas on the coast only 0 5 per cent were pneumonic cases in the sierra there were approximately 25 per cent

Bearing in mind that each one of these clinical forms may develop into the other types it is convenient to define the original clinical pictures with

development of fever and at times preceding it there occurs an intense frontal headache at times almost unbearable and resembling migraine

Nausea, followed by vomiting at first mucous later bilious is an early symptom this may disappear or persist throughout the course of the sickness Essentially it is of nervous origin exceptionally only is it due to gastro intestinal causes The same is possibly true with the **diarrhea** and **constipation** The diarrhea is fetid at times dysenteric and at times choleriform the latter is more frequent in the septicemic cases The **tongue** shows a creamy or whitish central coating with the tip and borders clean and red The coating is dry with a mother of pearl or porcelain like luster which finally becomes *coffee colored or yellowish ("sulfur tongue")* and at times even almost black The lips gums and teeth are covered with sordes The tremulous tongue is protruded with difficulty Symptoms real or apparent and signs related to the digestive apparatus are anorexia or a voracious appetite thirst which is often very intense injection of the fauces pharynx and palate inflamed tonsils covered with a membrane dryness and burning of the throat a fetid yellowish diarrhea

Respiratory symptoms usually are not notable except in those grave cases in which a developing pulmonary edema causes a marked dyspnea with as high as 30 to 50 respirations per minute The patient constantly complains of thoracic oppression and constriction especially retrosternal pain Cough appears late and produces only slight sputum which is at first viscous and later purulent but without blood which is almost always present in pneumonic cases *Physical examination of the lungs shows congestion* and bronchitis Late in the course of bubonic plague especially in the less acute cases a secondary pneumonia may develop recognizable by the accentuation of the described symptoms by diminution of vesicular breath sounds by crepitus and by aggravation of the general condition These secondary pulmonary localizations are not as serious as primary plague pneumonia and many of the patients recover However this is very important in the genesis of epidemics of plague pneumonia

In the **cardiovascular system** the alterations are not intense at the beginning and may even be entirely absent in benign cases In toxic patients there are precordial oppression and *tachycardia of from 110 to 140* per minute not always in relation to the degree of fever and the fall in arterial blood pressure The initial tense pulse soon becomes weaker and more frequent then dicrotic then anacrotic with disappearance of the rebound wave and finally thready intermittent and so imperceptible that it cannot be counted Sudden death due to cardiac failure may occur at any moment in the course of the disease and sometimes during convalescence Cardiac sounds are weak but otherwise normal The septicemia may be detected *in the blood* even in benign cases and before the appearance of fever A polymorphonuclear leucocytosis with neutrophiles predominating is the general rule

***Nervous system** symptoms are very important* as they give an indication of the apparent severity of the cases although those with the most marked

those which contribute most in defining the general aspect and the apparent or real gravity of the cases The **fever** develops sharply the body temperature *rising to 40° to 41° C (104° to 105.8° F) and sometimes higher* The maximum temperature is usually not reached during the first 24 hours but in the afternoon of the *second or third day* *The fever may run an irregular* course, but usually there are daily morning remissions Between the third and fifth days there may be a considerable drop in temperature, as much as two or three degrees centigrade (Valassopoulo 1901, Simpson, 1905) followed by a secondary rise which may reach or pass the previous level with a renewed intensity of the symptoms In one or two days more the fever again

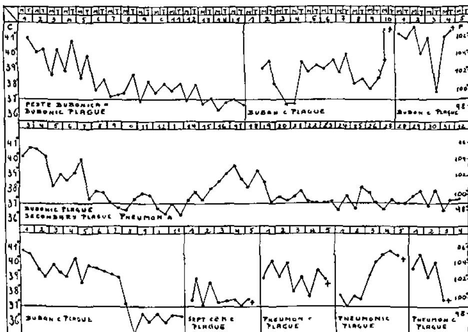

Fig 151 —Temperature curves in bubonic plague secondary plague pneumonia septicemic plague and pneumonic plague

diminishes and morning remissions occur These are each time more accentuated, with the afternoon rise in temperature less every day until in five to eight days a normal temperature is reached or there continues only a slight hyperthermia In some cases the temperature remains above normal for ten or more days Late temperature rises are usually due to complications

The **temperature curve** is not of great prognostic value although fever is higher in serious cases A sharp fall in temperature with increase in pulse rate is a bad prognostic sign and when due to collapse, results in a rapidly fatal termination A gradual decline in temperature is a sign of a normal course Toxic cases may show hypothermia In benign cases there might be no elevation in temperature during the entire course With the

Fig. 152—Primary cutaneous plague lesion (plague carbuncle)

Fig. 153—Primary plague carbuncle overlying submandibular bubo

nervous signs are not always necessarily fatal Symptoms of nervous system involvement are rarely lacking in serious cases but they may be insignificant with relation to the gravity of the lymphatic signs they vary from one case to another and during the course of the disease some being transitory and others continuous

In the beginning there are depression vomiting nausea headache a staggering gait difficulty of speech with stuttering insomnia restlessness and at times a tendency to wander even from one town to another Later motor and sensory involvement is the rule although this is not always grave The general aspect of the patients depends in large measure upon the degree of nervous involvement At times they appear semiconscious and mentally con fused answering questions with difficulty with slow hesitant speech leaving words and phrases unfinished and with stuttering The mental confusion may progress to complete cloudiness hebetude and stupor The patient mutters incoherent phrases in a voice almost inaudible Delirium continuous or inter mittent is passive although crises of excitation may occur When quiet patients lie immobile lethargic although conscious with the eyes half closed and fixed the mouth half open the relaxed facial musculature giving an expression of apathy or resignation This appearance may change into that of a profound intoxication of fatal prognosis

More commonly in the actively sick the face is congested and swollen the eyes brilliant sunken the conjunctivae injected the expression anxious restless and at times expressing pain or fear When hallucinatory delirium with excitation occurs and the expression becomes menacing or terrified the sick person may go to the extreme of committing suicide or homicide Pa tients in this state often flee from their homes or hospitals

In very severe cases a lethargic or comatose state develops with a total loss of sensibility these are signs of impending death The plague *facies* therefore is neither uniform nor constant and depends in large part on the toxicity of the infectious agent

Difficulties in the motor system appear early or late and consist of trembling muscular spasms convulsions contractures and preagonic carphol ogy In other cases the *facies* is determined by the degree of muscular relax ation

Sensory alterations are variable and include cutaneous hyperesthesia dull ing of the sense of hearing (at times more apparent than real) speech diffi culty alterations in the sense of taste intense thirst etc

Obviously plague has multiple nervous manifestations In India and China types with delirium and stupor are the rule In Africa and especially in South America these symptoms are lacking in the great majority of cases The classical descriptions of the Black Death of the Middle Ages are surpris ing in view of the number of curious nervous symptoms then described but which are not now seen

Cutaneous lesions of bubonic plague may occur early or late with very distinct pathologic significance Primary cutaneous plague the lesion of

becomes umbilicated breaks and dries forming a blackish scab finally a pustule is formed which drains a watery liquid The gangrenous center of the ulcer is dark colored and hard whereas the borders are raised and clear cut violaceous with surrounding edema

The primary carbuncle precedes the bubo by one or more days or is simultaneous with the bubo *and is usually localized near the ankles or wrists It* has been frequently observed in some Peruvian epidemics though totally absent *in others it has a benign prognostic significance*

In the course of the disease cutaneous manifestations are general (dry and burning skin or in very toxic cases a cold and pallid epidermis) or localized the latter being the more important although they are seen only in certain epidemics and in certain regions being notably absent in others The lesions seen are petechiae ecchymoses pustules (varioloid) and gangrene They have been given the general term "carbuncle Petechiae of variable size may appear over the buboes or independent of them especially on the abdomen or extremities They are dark similar to the ecchymoses which distinguishes them *from the generalized pustular plague eruptions that at times* resemble smallpox (plague variola) More often dark pustules (carbuncles) *appear after the development of the bubo are not very numerous and occur* in any part of the body and in any period of the disease These lesions may develop like the primary plague carbuncle *with a tendency to scarring or* they may extend into the subcutaneous tissues and involve a large inflamed area with necrosis from the central depths to the surface leaving a leathery indolent ulcer with firm edges and of varying depth and size When they exceed the usual size which is from 2 2 to 5 cm in diameter they may expose the aponeuroses the muscles and even the bones These great necrotic cutaneocellular ulcers occur most often in the gluteal and scapular regions Their prognosis is generally benign

The late pustular eruption is due to emboli of plague bacilli of low toxicity The late developing plague carbuncle is rare in South America but such is not the case with the so called "plague smallpox or plague variola *which has been reported in Chile* (1903) and very frequently in Ecuador

It is not uncommon to see extensive necrosis of the skin at the sites of the lymphatic glands accompanied by petechial eruptions circulatory disturbances (elephantiasis) marasmus etc *usually with fatal termination*

Of all the symptoms and clinical signs of bubonic plague the most important are those related to the **bubo** an indication of involvement of the lymphatic system In so called ambulatory plague the bubo may be the only sign of disease In the disease *ingua de frio* (cold bubo) of Brazil which corresponds to this type we have proved bacteriologically its plague etiology (1941) Epidemics of ambulatory plague have been observed in *the north* east of Brazil and in Ecuador The so called benign plague formerly called *pestis minor* or *aura pestilentialis minor* or *minior* is more frequently seen *this* manifests itself by early vague symptoms—slight fever headache conjunctival

inoculation was clearly described during the Black Death and the Great Plague of London At the present time it is less common being observed usually in relation to benign epidemics (Peru) Many of the classical texts

Fig 1ȷ4 —Plague cacl x a Typical bubonic case n tiated months prior to the photograph Left femoral bubo suppurated leaving indolent ulcer Generalized cutaneous petechiae and ecchymoses Interference with lymph drainage in right leg

of recent times do not even describe it It begins as a red macule which becomes papular and spreads with the center taking on a blackish hue (plague carbuncle) In the center a phlyctenule develops filled at first with clear serum which later becomes hemorrhagic and at times purulent The vesicle

described in which the tissue loss is so extensive that cavities are formed in which may be seen vessels nerves or bone

The most important localizations of the buboes are

1 In the inguinal region either near the crural arch (inguinal buboes) with the axis directed obliquely toward the middle line and downward or in any part of Scarpa s triangle (femoral or crural buboes) with the axis vertical Inguinal buboes may be partially intra abdominal The periglandular edema often extends to the abdominal wall or down the thigh as far as the knee *Even in the benign ambulatory cases it is possible to detect the infected persons by noting the limp corresponding to the extremity in which the bubo is located*

2 Buboes may occur in the iliac region The diagnosis is difficult when there is no accompanying inguinal bubo cases have been mistakenly diagnosed as appendicitis and patients subjected to operation (Macchiavello 1932)

3 Axillary buboes are usually accompanied by an extensive soft edema which advances from the breast as far as the neck and toward the deeper parts which may interfere with respiration The patient lies on his back with the arm abducted from the trunk Many times involvement of the subpectoral glands favors secondary pneumonic localization (Gaud and Jorge 1933)

4 Cervical buboes may be retroauricular submaxillary supraclavicular etc Edema is variable and may be almost absent or very extensive reaching the face or the thorax and at times involving the larynx and pharynx Two types of cervical glands must be distinguished *with relation to their origin* and prognosis those which arise from *tonsillar plague* or *plague angina—very frequent in the sierra of Ecuador* (Martinez Vinueza 1930) among the Indians who kill fleas and lice with their teeth—cases which commonly terminate in pneumonia and in which the tonsillar inflammation is enormous (de Souza 1913 Brites 1922) and those which derive from a cutaneous point of entry these are evidently more benign

5 Epitrochlear and popliteal buboes are less frequent and usually occur in cases with multiple localizations

Double and symmetrical buboes are a frequent finding At times they are multiple located in different places they may appear simultaneously or one after the other in neighboring or widely dispersed areas the former due to lymphatic progression of the infection and the latter to hematogenous spread

Of the types with multiple localizations note the syndrome described by Macchiavello (1941) called multiglandular plague fever It is characterized by a septic fever curve attenuated plague bacteremia *and a secondary septicemia* caused by nonvirulent microorganisms The course is prolonged for a month or more *during which time there appear* successively from 4 to 14 or more variously situated large buboes There are alopecia cachexia and slow *recuperation* with a prolonged convalescence or death may follow

congestion dizziness and vertigo—the significance of which is made clear by the appearance of the bubo although this is not accompanied by much pain nor by the characteristic inflammation In a week or ten days the bubo is reabsorbed or suppurates or becomes indurated A chronic form of benign plague was seen in northeast Brazil (1941) the buboes whether suppurated or not or whether softened or woody showed periodic inflammatory exacerbations which did not interfere with the patients occupations although they *caused a certain degree of debility and anemia In pestis minor the patient may be ambulatory or may take to his bed for one or two days rarely longer*

In grave cases the bubo is a notable sign which may usher in the clinical course even before a rise in temperature Commonly however the bubo occurs simultaneously with or later than the fever and it may appear very late The patient feels a sharp pain in the lymph gland area where the bubo will develop a pain which may be so intense as to mask the other symptoms Soon one or more enlarged glands appear which separated at first soon fuse into a single mass which makes up the bubo a mass which grows slowly or rapidly reaching variable sizes from the size of an almond to that of an orange usually about the size of a walnut or a hen s egg The smaller buboes are usually more painful and serious Around the bubo there develops an inflammatory zone of varying size it is hot hard reddened edematous and painful to the slightest touch Soft edema and mild inflammation usually accompany the largest buboes The inflammatory edema reflects the periadenitis and subcutaneous congestion which at times develop into a bloody effusion This entire *clinical picture requires one to five days for development and usually* daily changes in its evolution are noticeable

The shape of the bubo is oval or round the surface is irregular At first more or less free in the subcutaneous tissues it soon becomes fixed and adherent to the neighboring tissues The superficial consistency is pasty deeper it is firmer Over the bubo the skin is smooth tense red hot swollen and does not crease Rarely in South America but more often in other countries there appear over the bubo hemorrhages and phlyctenules carbuncles petechiae processes which occasionally go on to ulceration and gangrene Deep buboes and large superficial buboes are usually accompanied merely by a simple local sensitivity on palpation or pressure After a variable number of days the inflammatory signs and pain diminish the bubo softens or indurates or is reabsorbed or breaks down and suppurates When reabsorption takes place the pathologic process has a sequence inverse to that occurring in its formation leaving as a residue indurated glandular tissue and pigmentation of the skin When induration takes place the entire gland becomes woody or perhaps only one part or several parts which alternate with zones which are more or less soft or softening In cases of suppuration the skin becomes thinned over the gland which opens spontaneously between the seventh and fifteenth days draining a granular pus for a variable time in ordinary cases from 10 to 15 days In other cases the suppuration may last one or two months and is accompanied by tissue necrosis of varying degree cases having been

Renal manifestations in the course of bubonic plague are inconspicuous and usually are overlooked. The urine is scanty, highly colored, low in chlorides and urea, with albumin and at times cylindruria and even hematuria. Retention of urine is seen rather frequently, but anuria is *exceptional*. *Elimination* of plague bacilli in the urine has been reported.

Evolution and Termination

Bubonic plague usually has a course of 6 to 8 days if it does not terminate fatally. Between the sixth and seventh days the fever may recede accompanied by sweating, with favorable changes in the *facies* and in the general condition, pulse rate, and psychic manifestations. Buboes which have sup*purated heal with scarring* between one week and a month. Convalescence does not always accompany improvement in the symptoms, the patients often continuing in a debilitated condition although afebrile. There is very often a false impression of improvement, but the pulse soon becomes rapid and small, fetid diarrhea begins, and dyspnea, sweating crises, insomnia, apathy and *weakness are all increased. The buboes drain an abundant fetid pus* without any tendency to scar formation, the patient finally dies after the twentieth day.

Death nevertheless usually occurs within the first few days. In fulminating cases it may occur in 12 to 24 hours, in grave cases in from 2 to 3 days. Death usually occurs before the sixth day from toxemia, cardiac failure, cerebral involvement, or secondary causes such as hemorrhage, asphyxia, etc.

A certain number of cases of bubonic plague in one epidemic or another develop a secondary plague septicemia. *It is possible that all bubonic cases* except the ambulatory develop a plague septicemia or bacteriemia at one or another period.

Complications

Complications are frequent, and a few, as the pulmonary, are exceptionally important. They include pulmonary edema, bronchitis, pleurisy, *pneumothorax*, and above all secondary pneumonia. The origin of this secondary pneumonia is as follows: *Past. pestis* reaches the lungs from any *lymphatic* region; it enters the thoracic duct and passes into the left subclavian vein giving rise to pulmonary emboli which act as a substratum for focal broncho*pneumonic processes, at times* becoming confluent with a secondary plague pneumonia. Usually this process requires a bacterial strain of great *invasive* power and slight toxigenicity, combined with a lengthy survival time of the patient. *It is a fact that the secondary pneumonias* appear late in bubonic cases of mild evolution, and under circumstances which *facilitate the* extension of the infection by way of the lymphatics, such as physical exercise. Macchiavello and Uriguen *(1944)* have reported experimental proof of the foregoing. Additional complications which have been *described include* gastrointestinal upsets, abortion with death of the fetus, arthritis, conjunctivitis, *corneal ulcer*, various hemorrhages, chronic plague, and *marasmus*. By

Fig 15 Inguinal bubo Common plague facies

Similarity to yellow fever can be judged from the fact that often in dealing with these cases the Brazilian Yellow Fever Service has been mistakenly requested to control yellow fever

We have recently been able to confirm the existence of benign or ambulatory cases of plague septicemia (Peru) characterized by the absence of buboes a feeling of intoxication oneiric delirium and at times fever which does not last more than one or two days The usual diagnosis of these patients is benign grippe but blood cultures revealed the presence of very attenuated strains of plague bacilli

PRIMARY PLAGUE PNEUMONIA

Primary plague pneumonia is even more serious than plague septicemia In epidemics it spreads from person to person either by direct contact with individuals engaged in the commercial handling of skins of wild rodents in areas where sylvatic plague exists or from an original case of secondary plague pneumonia in a bubonic case Transmission occurs from person to person by droplet infection The evolution may be fulminating with death in a few hours or death may occur between the second and fifth day of sickness the average survival time (Wu Lien teh 1936) in the epidemic at Harbin being 1 8 days in 1 128 cases The clinical aspect depends on the gravity of the infection but in general the patient does not lose consciousness even when delirious Symptoms and signs observed most frequently are fever which remains high until death malaise restlessness a feeling of retrosternal constriction cardiac failure and terminal cyanosis The pneumonia is indefinite difficult to auscultate and percuss and lobular at the beginning although it may become lobar later The paucity of physical signs is in contrast to the grave clinical picture even when in reality the patient does not appear to be suffering (Wu Lien teh 1926) The principal signs are cough with a scanty viscous blood tinged sputum which later becomes more fluid bright red and loaded with plague bacilli (Murdock 1939) The contagiousness of these cases is enormous after a noninfectious period of 24 to 48 hours (Zabolontny) when the cough has not yet begun The mortality is practically 100 per cent so that one doubts the diagnosis in any case in which the patient recovers The diagnosis in early cases may be suspected when one encounters a patient with an atypical pneumonia and in whom the dyspnea and marked tachycardia and at times the gravity of the clinical picture cannot be explained on the basis of insignificant pulmonary signs

DIAGNOSIS

The diagnosis of plague in any of its forms is simple if the existence of plague in the locality in epidemic or endemic form is known Nevertheless every time plague has invaded a country it has given rise to extensive debate The initial clinical picture of bubonic plague can be confused with any acute infection The bubonic forms require differential diagnosis from other glandular diseases especially those of acute venereal origin Primary plague septi

marasmus we mean a progressive emaciation accompanied by stupor and profound weakness On the other hand in chronic plague the patient has apparently mild symptoms but may die with visceral abscesses in the spleen liver or lung similar to the chronic plague of rodents The buboes may be complicated by secondary pyogenic infection abscesses skin furuncles A true plague meningitis has been seen on rare occasions (Lafont et al 1915 Paso 1925 Godinho 1907 Sauhueza 1907 Meyer et al 1937

The sequelae of plague are nearly always temporary and related to the nervous system (aphasia dementia ataxia) to the skin (gangrene) or to the sense organs (blindness)

An attack of plague is supposed to leave a permanent immunity Simpson however (1905) cited several cases of a second attack with the second not always the more benign some cases terminating fatally

PRIMARY PLAGUE SEPTICEMIA

Cases without buboes, and with *Past pestis* present in the blood stream are held to be **primary plague septicemias** They are generally more serious than the bubonic cases Many cases catalogued as septicemic have deep buboes which are typical but which are not diagnosed during life In true plague septicemia the glands are slightly hypertrophied and inflamed as a consequence of the generalized hematogenous infection However the blood stream invasion may be so sudden and acute that the sickness may end in death even before 24 hours with no involvement of the lymphatic system Most commonly the clinical aspect is the same as that of a grave bubonic case with numerous nervous symptoms and no bubo In very toxic cases the temperature is moderate the facies pallid the general aspect anxious or stuporous with a thready pulse and intense dyspnea after a final period of coma with relaxation of the sphincters carphology etc the patient dies But few cases of typical plague septicemia recover at times a late bubonic localization occurs secondarily and all symptoms regress until recovery takes place The percentage of septicemic cases in Asia is quite high—up to 30 per cent In America the primary septicemic form is exceptional and at most includes less than 5 per cent of the cases

So called **gastrointestinal plague** which is related to the septicemic form includes various types Hojel in Bombay described a typhoid form with epigastric pain abdominal tension rachialgia hypertrophy of the liver and spleen abdominal petechiae a typhoid state and involvement of Peyer s patches without concomitant lesions in the mesenteric glands Wilm, in 1896 in Hong Kong described a violent gastrointestinal form accompanied by mesenteric gland involvement but without external buboes In Brazil in 1941 we saw an amarillic form apt to be confused with yellow fever because of the icterus the color of the vomitus and the general symptoms which were especially violent in the digestive apparatus (hemorrhages hematemesis melena vomiting and violent diarrhea) with complete absence of buboes

doses (100 cc intravenously followed by one or more similar injections at 6 hour intervals if necessary) Serum improves the general condition of the patient and lengthens the average survival time but usually it does not prevent a fatal outcome except in a small percentage of cases The serum therapy has proved of no definite value in South America and at times there is a higher mortality among the plague patients treated with specific serum than in the control cases and a very high incidence of anaphylactic phenomena similar to serum sickness We do not advise the use of serum except in grave cases treated before the second day of the disease excluding the septicemic and violent pneumonic forms in which we feel that serum is useless

Penicillin in the treatment of plague has not been extensively studied This also applies to streptomycin although Hornibrook (1946) has obtained promising experimental results in plague mice He also found that streptomycin inhibited the growth of *Past pestis* in broth in a dilution of 1 160 000 A preparation containing 200 000 units per gram was used It was tested by Sokhey with excellent results in India (1948)

PROPHYLAXIS AND METHODS OF CONTROL

From the epidemiology and the clinical course of plague it can be concluded that methods of prophylaxis and control should be based on one of the following points methods against rodents methods against fleas and methods relating to human beings sick or well In all countries where plague is an important sanitary problem these methods are under the jurisdiction of official services of public health and many of them have been incorporated into international conventions (the International Sanitary Convention of Paris 1926 with the recent modification under the auspices of UNRRA and the Pan American Sanitary Code which include the early agreements of the Washington Convention 1905)

The methods used against rodents vary considerably, depending upon whether one is dealing with wild or domestic species Since the living habits of the former are so variable it is not possible to outline a general plan of action but trapping poisoning shooting destruction of burrows fumigation etc may be found useful In certain regions it may be advisable to provide direct means of individual protection as in the case of persons hunting for skins and others who for whatever reason must come into direct contact with these rodents

Antirat procedures include all measures used to make buildings and dwellings rat proof

Deratting measures may be applied in any situation where the destruction of rodents is necessary such as ships ports cities fields and sylvan areas The principal methods of deratting are fumigation (which by certain methods destroys fleas as well) trapping and poisoning

Fumigation may be performed with carbon monoxide ethylene bichloride sulfur derivatives (sulfurous anhydride) and especially with hydrocyanic acid which may be made in situ with potassium or sodium cyanide and sulfuric

cemia may be suspected but not proved clinically without bacteriologic confirmation This also applies to plague pneumonia

Definite diagnosis is usually made by means of the specialized public health services For those who wish to make their own diagnoses the suggestions we have recently made (1945) concerning the identification of *Past pestis* and the procedure of Webster transcribed by Wu Lien teh et al (1936) are recommended In general definite diagnosis is based on the presence of *Past pestis* in the suspected material—lymph gland pus blood or sputum—which may be detected by direct examination of stained slide by inoculation into susceptible animals (guinea pigs are most useful) and by culture A combination of the three methods is preferable

PROGNOSIS

In India the bubonic form has a mortality rate of 60 to 90 per cent in America it can be as low as 15 per cent although usually it is around 35 to 40 per cent The septicemic form has a mortality rate of 90 to 95 per cent and the primary pneumonic form 100 per cent

TREATMENT

Up to the present time the nonbiological treatment of plague has been ineffective except for symptomatic measures—rest in bed cleanliness purgation hydrotherapy in cases with hyperpyrexia antipyretics when there is no cardiac involvement cardiac tonics morphine as a sedative etc The sulfonamides recommended by Schutze (1939) Carman (1938) Chopra (1941) Villafañe Lastra et al (1941) Plum (1942) Burga Saavedra (1942) Wagle et al (1941) Sokhey (1940) Savino and Morales Villazon (1942) Durand (1939) Girard (1941) Wayson and McMahon (1944) etc both in experimental animal plague as well as in the human disease and especially sulfathiazole and sulfadiazine appear to give good results in bubonic and septicemic plague At the present time sulfadiazine is recommended we have had even better results experimentally with sulfamerazine A sufficient dosage must be given to maintain a sulfonamide blood level of 15 to 20 mg per cent during the first 4 or 5 days of the disease The initial dosage recommended should be equivalent to 4 Gm (60 gr) of sulfadiazine with subsequent doses of 2 Gm every 4 hours day and night until the fever drops and thenceforward 0 5 Gm every 4 hours until the fifteenth day The author (1946) is of the opinion that the statistics collected in South America on the value of treatment are not very convincing and believes that in many benign epidemics drugs have been applied so indiscriminately that part of the mortality is due to abuses in treatment

With regard to the biological treatment of plague the use of bacteriophage has proved to be ineffective With regard to the use of hyperimmunized horse serum in plague (antiplague serum) we personally share the point of view of Chosky that it is useful only when applied early in large

acid, or purchased in a liquid state in steel cylinders, or absorbed in aluminum earths or on special paper discs, or in the form of calcium cyanide

Eradication also can be accomplished by toxic gases applied to the rat burrows (calcium cyanide) or by the use of flame throwers, introduced by Donovan and Hopkins in cooperation with Long (1941) Traps of the snap or "guillotine" and wire cage type are used

Poisoning is carried out with baits attractive to rats flour, fish, fruits crackers, liquids, etc The continual use of the same bait as a vehicle renders it ineffective, since the rats stop eating it in a few days The poison used preferably is white arsenic in 18 per cent strength In other places the use *of phosphorus has become more popular (Darvault paste,* Danysz paste, Schattermann's poison etc) barium carbonate, red squill, strychnine, potassium cyanide, thallium sulfate, and gypsum (which acts by hardening in the rat's stomach) We believe that the introduction of sodium fluoroacetate called "1080" (a rat poison developed by North American investigators), opens a new path in rodent poisoning (Ormsbee, 1945, *Johnson*, 1945, Kalmbach, 1945)

Methods against fleas include many of those employed against rats such as flame throwers *in* rat burrows *and* on floors, cyanogen gas *in* rat burrows, hydrocyanic acid gas on ships etc Repellents have also been used, such as kerosene, cresol, and others, all of which are of only temporary effectiveness The introduction of DDT (Zeidler, 1874 Muller 1939 Orlando Laboratories, Florida, 1944) has opened a new field in the fight against the vector of plague Similar new *insecticides* such as Gammexane or "666," the gamma isomer of hexachlorocyclohexane, have similar effects (Slade, 1945)

Working in cooperation with the National Anti Plague Service of Peru, the author has applied to the prevention and control of plague the two most powerful arms which we have at the *present* time as insecticides and rodenticides, respectively—DDT and "1080" or sodium fluoroacetate. "1080" and DDT may be used advantageously as well in the control of sylvatic plague Another poison recently introduced, which appears to be effective especially against *R norvegicus*, is alpha naphthyl thiourea (ANTU), a drug which in small doses produces a marked serosal exudation into the thoracic cavity The repeated application of this poison produces a high degree of tolerance It acts as a contact poison as well as by ingestion (Richter 1945) McClosky and Smith *have studied the pharmacology of this chemical* (1945)

Methods used with relation to human beings vary, dependent *upon* whether one is dealing with well people or with patients sick with plague Personal prophylaxis consists in (1) Avoidance of the infection (2) Protective vaccination either with suspensions of avirulent living microorganisms (the vaccines of Otten and of Girard) *or* with vaccines made with killed plague bacilli (especially the Haffkine) This *is* not the place *to discuss* the value of these procedures, but if they are used, the recommended dosage must be employed according to the indications (3) The application of antiplague serum as a preventive We believe that this last procedure should be reserved exclusively for very special cases, since the reactions caused by the *sera, at least those available in South America*, are often severe

which this expression suggests) Each epidemic inspired additional concepts of the etiology, as when Scott, in 1832, decided that a soldier in his command "generated this disease within him by a fit of intoxication," and that it was "intemperance which generates and spreads the calamity" (Phalen, 1942) Snow (1855) collected evidence of the distribution of cases in London which pointed directly to the cause in water supplied from a certain pumping station and did not hesitate to draw conclusions He was perhaps the first investigator to demonstrate that water, rather than air, was the medium of transmission Scott (1939) refers to a discovery by Pouchet, as early as 1849, of vibrios in the stools of cholera patients The definitive demonstration of the cholera vibrio is attributed to Koch (1883) Unfortunately it was attended by considerable disbelief and confusion owing to nonpathogenic vibrios which were also detected and some matters such as the real significance of the El Tor vibrio, remain disputed by bacteriologists to the present day

The earliest efforts to treat cholera utilized anything that could be conceived to have virtue, from drugs to physical therapy, and while a certain proportion of victims survived both the disease and the treatment, there was and is nothing to suggest that anything was gained Saline, however, was injected as early as 1831 by Thomas Latta (1831 1832) Doubtless the dosage was insufficient in these early trials else the importance of fluid would have been appreciated half a century sooner It was not until 1909 that Rogers (1915) used saline in the amounts now generally employed, which alone has been the decisive feature of treatment as it remains today The 1947 epidemic in Egypt gave opportunity to try a great number of sulfonamide derivatives, several of which seemed to reduce mortality somewhat when given early enough in the course, although statistical proof is not striking, but even then it was obvious that Latta's treatment was the indispensable determining measure In the 1947 epidemic, also, there was demonstrated a specifically effective method of restoring kidney function in uremic subjects with testosterone and, in consequence of this, in such cases there was what some have regarded as an outspoken reduction in mortality

From the seventh century to the present day, cholera has existed in the region of the Ganges delta and has been disseminated from there to the entire world Effective measures have almost entirely excluded it from the West and much of Europe but the Near East continues to suffer periodic outbreaks, supported, probably, by now well established local stores of the vibrio Transmission of the disease is so well understood and is nominally so readily subject to effective control, that one might expect that the disease would have been eradicated for all time in India and eventually in the entire world That [illegible] explained freely in various ways, and there are even tho[illegible] as a source of relief from "overpopulation" Tw[illegible] newborn, have the opportunity to succeed on their own behalf where for centuries others have failed, and the next few years will show whether in time to come there might not cease to be such an appalling thing as epidemic cholera

ETIOLOGY

Vibrio comma is a bacterium of the order Eubacteriales, family Pseudomonadaceae, which includes only the vibrios and Pseudomonas as of clinical interest (Breed et al, 1948) Of its tribe, Spirilleae, vibrio is the only known pathogen and although vibrios are quite numerous, only one pathogen *Vibrio comma*, is recognized This species has been divided into three strains Inaba, Ogawa, and Hikojima, the virulence of which is undisputed, but it also includes "another vibrio" known as El Tor, which has appeared at times as a pathogen beyond doubt, and at other times as an object of terrible perplexity (Linton 1940)

CHAPTER 28

CHOLERA (ASIATIC CHOLERA)

EDWARD HENDERSON AND HARRY SENECA

DEFINITION

Cholera is an acute, infectious, systemic disease caused by a specific organism, *Vibrio comma*, and characterized by an overwhelming diarrhea, nausea, and vomiting, followed by dehydration, medical shock, and renal insufficiency, with a dramatic course and high mortality It is endemic in parts of the Orient, particularly India and China, and has appeared in epidemic form in many other parts of the world

Synonyms—Various terms which refer to cholera in general are Asiatic, Indian, epidemic, malignant, pandemic, spasmodic, and pestilential cholera Old clinical terms such as asphyctic, algid, typhoid, and automatic cholera refer to clinical forms in which the several manifestations seem to predominate A less acute disease which has been attributed to other vibrios is known as bilious, European, simple, or sporadic cholera, or *cholera nostras* Unfortunately the name *cholera* has been loosely given to numerous diarrheas of impressive severity, none of which is cholera, hence we have "winter" and "summer" cholera, *cholera morbus* (acute gastroenteritis), and *cholera infantum* (summer diarrhea in children)

HISTORY

An early description of diarrheal disease attended by very high mortality occurs in the Indian writings of Susruta in the seventh century One naturally looks to India for early recognition of this disease However, other enteric diseases doubtless depopulated the ancient world if not nearly so well as cholera and none of the historic descriptions of epidemic diarrhea, prior to the nineteenth century, wholly rules out other diagnoses During the nineteenth century, the world was shaken by repeated, authentic pandemics of cholera which originated in India and traveled by land and sea routes throughout Asia, and, aided by religious pilgrims and the Suez Canal, throughout Europe and as far as the United States Napier (1943) presented a map of the world in which is traced the course of travel of two of the early epidemics

The first pandemic began in 1817 and extended to Asiatic Russia, Persia, Arabia, Ceylon, and the Far East The next, in 1826, involved, in addition, all of Europe (1832) and localities in the United States (1836 1838) Successive pandemics originated in India in 1842, 1863, 1879, 1891, and 1902, and each spread widely, but thereafter effective control measures were instituted by many countries and cholera ceased to be world wide No outbreak occurred in the United States after 1873, and quarantine in this country was effective from 1911 Elsewhere the disease continued to flare, as in parts of Europe and especially Russia, and in the present century small epidemics have been seen in the Philippines as recently as 1935 1936 The most recent notable epidemic (anonymous, 1947) appeared in Egypt in 1947, it consisted of more than 20,000 cases, with an admitted mortality of 48 per cent

The disease was long attributed to a poison of oriental origin, transmitted by the air, i e, a miasma (In the Arabic language, cholera is called *hawa asfar*, "yellow air" Apparently the ancient Arabian physicians associated the disease with filth, decay, etc.,

1947), but not conclusively (Gohar, 1948b) Butter appears definitely to have transmitted the disease (Grattan, 1939) Likewise the question whether or not vibrios can survive in the soil, and under various climatic conditions, has been studied (Sanyal, 1941), and it has been concluded that moist soil containing an optimum concentration of nitrates and organic matter is capable of harboring the organism for long periods

Variation

Like many other organisms, the cholera vibrio readily becomes adapted to any environment in which it can survive at all Sufficiently prolonged cultivation, as upon laboratory media, yields organisms differing in carbohydrate and protein composition from the parent strain, that is, "variants" If specific antisera are contained in the medium, the serologic specificity of intact, virulent "smooth" organisms is abolished, and there result the metabolically inactive, more generalized, "rough" forms Phage has a similar effect. An extensive literature has classified the native vibrio (as obtained from patients with cholera) and its subsequent variations, using metabolic and serologic criteria That such variations are equally possible in nature must be emphasized They would explain the progressive increase in virulence during an epidemic and the change from low to higher virulence in carriers.

Immunologic Types (Heiberg 1935, Linton, 1940) —The original or Inaba vibrio is accompanied even in the same epidemic by the Ogawa type or variant (Felsenfeld, 1939b Pasricha, 1942, Soman and Naik, 1945), as well as the "intermediate" Hikojima type (Fournier, *1940*) In any collection of vibrios (Burrows et al, *1946*) or in vibrios collected in any one region (Felsenfeld, 1939b), there is found a varying proportion of each of these, together with El Tor vibrios The fact that not all El Tor vibrios fall in the O antigen group I has been mentioned, notwithstanding the group I antiserum has practical diagnostic value as revealing some 85 per cent pathogenic strains (Taylor, 1936) This method of typing has been carefully studied (Burrows et al, 1946) The possibility remains however, that any type may change over into another, and what have been regarded as types may not be more than variants (Shrivastava and White, 1947)

The El Tor Vibrio

Older literature discusses at length whether this vibrio is ever a pathogen It is a proved cause of clinical cholera, in localized epidemics, as in Celebes (DeMoor, 1938, 1939, van Loghem, 1938) in 1938 and 1940, and in East Africa (Marras, 1938) It makes slight difference practically whether such outbreaks are termed "choleriform" merely because the organism is more hemolytic than expected of a proper cholera vibrio—especially when the metabolic and serologic criteria conform so closely

The El Tor vibrio may be pathogenic in one locality and not in another (Abdoelrachman, 1944, 1945) It may include "types" within its "type" (van Loghem, 1946) It *has repeatedly been described (Read and Pandit, 1941*, Venkatraman et al, 1941) as occurring in the absence of clinical cholera, in patients having food intoxication (Kato 1941) and in patients with gastroenteritis, which it may have caused (Felsenfeld, 1939a) *Thus* it is not unreasonable to think of this vibrio as a type of *V comma*, susceptibility to which varies more greatly than to the other types The occurrence of epidemic cholera proves that the susceptibility of the host, and the virulence of the El Tor vibrio, can reach the same degree as with other *V comma*

The hemolytic power of the El Tor vibrio, on which its identification relies in part, is generally greater than that of the so called nonhemolytic vibrios but the distinction is far from absolute Even recognizing the difference between "true hemolysis" (van Loghem, 1938, Bernard et al, 1939, Felsenfeld, 1944, Gohar, 1932, Kabeshima, 1918, Mertens and Beeuwkes, 1940, Read et al, 1942) and "hemodigestion" (Read et al, 1942), the hemolytic action that will be seen depends on the detailed technic used, the age of the culture, its history since isolation from the disease, and peculiar properties of the blood that is used (Otten, 1939) A "true" vibrio which has not grown in the laboratory for more than a

Synonyms—Koch's name for this organism was *Kommabacillus*. It is frequently designated by the specific names *comma*, *cholerae*, and *cholerae asiaticae*, thus *Spirillum cholerae asiaticae*, *Pacinia choleraeasiaticae*, *Microspora comma*, *Vibrio cholerae*, *Bacillus cholerae*, *B. comma*, or colloquially simple as the cholera vibrio.

Classification

At one time the effort to classify vibrios was concerned with the distinction between *V. comma* with some other chemically and antigenically similar vibrios and "other vibrios" of no clinical importance—so called groups A and B respectively. A tremendous amount of work has now reduced the problem to vibrios which although they have a common H antigen, can be distinguished by their O antigen as belonging to group I of a possible six groups (Gardner and Venkatraman 1935). Group I includes vibrios not hemolytic to goat or sheep cells, that is, "true" *V. comma*, and vibrios which are hemolytic, or at least more markedly and permanently hemolytic, than the preceding, that is, the El Tor vibrios. Unhappily, some El Tor vibrios are described within the other O groups, but this is not the only source of difficulty with this type strain or variant whichever it may be.

Morphology and Colonies

The cholera vibrio is a slightly curved rod 0.5 by 1 to 5 microns observed singly and in chains which tend to be spiral. It is gram negative and motile and has a single terminal flagellum. It forms small (1 to 2 mm), circular, slightly convex, moist, glistening, translucent colonies on solid media. These are yellowish white on gelatin, brownish white on agar and colorless (or later pinkish) on MacConkey's medium and are surrounded by a small zone of "hemodigestion" on blood agar. In broth there is a slight turbidity and also a flocculent precipitate with wrinkled pellicle. Gelatin is liquefied.

Reactions—It forms acid but not gas from glucose, fructose, mannose, galactose, maltose, sucrose, mannitol and (slowly) glycerol but not from lactose, arabinose, inulin, or dulcitol. The combination mannose+, sucrose+, arabinose− has been suggested (Heiberg 1935) as a determinant for *V. comma* but is not specific since the same type of reaction has been noted with other vibrios.

It is an obligatory anaerobe living at an optimum temperature of 37° C and an optimum pH of 7.6 to 8 with poor tolerance to an acid medium.

It forms indole and nitrite from nitrate and thus it gives the *cholera red* reaction provided reducing agents such as carbohydrates are not present in excess (Sen et al 1946). Hydrogen sulfide is formed. Starch is hydrolyzed actively at high pH. It is Voges Proskauer negative.

Resistance

To proliferate the vibrio must have water, salt and organic matter. It has been stated that it is easily (Napier 1943) or readily (Kahn 1942) killed by drying, nevertheless vibrios have been found viable four years after having been dried and sealed. The vibrio is also killed by overgrowth of other organisms as in water containing sewage. Optimum conditions appear to be about 1 per cent salt and 2 p p m peptone but the organism can survive for weeks in concentrations one tenth of these or less. It does not withstand temperatures above 42° C or below 14° C nor pH below 6 (nor it is said, above 9.4). Heating at 55° C destroys the vibrio after 15 minutes. The usual organic (phenol) and inorganic ($KMnO_4$, $HgCl_2$) poisons destroy it rapidly. Numerous races of bacteriophage including the specific races A and N, destroy the cholera vibrio.

Water in tanks is more conducive to survival of the vibrio than free running waters. Water which has been sterilized by autoclaving enables it to survive for 3 days or more, utilizing probably organic material which has been thus broken down (Lahiri et al 1939). *Foods of many kinds have been studied to determine whether the vibrio can remain viable* within or upon them, or can be transmitted by them. Dates have been considered (Yen,

conditions permit, until a *number of "animal passages"* have taken place in the human population. Some of the subjects may be *in poor health*, or some may be susceptible enough to experience a mild diarrhea, and the vibrios they discharge will have gained in virulence. Presently they *are found in sufficiently large* numbers to be detected in the stools. Soon the infecting dose and the virulence are sufficient to produce recognizable cholera *in a few persons*. *From this point the* extent of an epidemic is limited only by the facility with which vibrios can be transmitted *from one person to another*.

The carrier state is important in facilitating an unobserved transfer of organisms among *the population*. It is also important to the carrier himself, as antecedent to clinical cholera *at any time his* susceptibility may increase. Harboring the organisms does not confer immunity nor does clinical cholera preclude susceptibility at a later date. Carriers may show *no symptoms of the disease for a few days and yet later come down with the most overwhelming form of cholera*.

A person who is a carrier at one time may cease to show organisms and later again may *have them*. Whether this is necessarily the result of a reinfection, or whether the organisms *lurk in the intestine or gall bladder* so that the carrier state is actually much more prolonged than it seems, cannot be concluded. The situation is met in careful cholera control, by reexaminations of supposedly "negative" subjects.

Epidemic Characters

In India, the disease reaches its peak during the warm, rainy season when the humidity is high. As the humidity declines, the epidemic severity subsides until at 10 per cent relative humidity the disease reaches a standstill. This was likewise observed in Egypt.

The progress of an epidemic is related to the phage titers which are found. When phage is at a maximum, the epidemic comes to an end, while very low titers are seen during the height of an epidemic, when almost all vibrios isolated are typical and agglutinable. Vibrios surviving the action of phage become atypical, nonagglutinable, and, in due course nonpathogenic.

GEOGRAPHICAL DISTRIBUTION

The world distribution of cholera changes little from year to year; for many years it has been confined to India and the Far East, the exception is the appearance of epidemic cholera in the Mediterranean area such as the recent epidemic in Egypt. Cholera statistics are always somewhat unreliable (Seil, 1945). Reports vary in completeness but probably never exceed the actual incidence. Some districts may lack medical personnel entirely, and others may be reluctant to admit the presence of the disease even when it has been recognized since it is today a serious reflection on the very civilization that harbors it. Hence one may conclude that cholera is as prevalent as is shown, where it is shown to be prevalent, and one may suspect it to exist in any neighboring district, particularly when reports are lacking. The distribution, as it affects cities, might be misleading, since it is only in cities that cogent sanitary improvements exist, but cities necessarily have the burden of reporting many cases coming to them from outlying districts.

The division of India into Pakistan and India, while shown by boundaries, has no immediate influence upon the density of cholera throughout the region, and this has therefore been shown in a uniform manner.

Pilgrimages.—Since the turn of the century, cholera has been largely confined to the Far East, its spread westward to the Near East depends on religious pilgrimages to Mecca. Mohammedan pilgrims from India, the Far East, and the East Indies, where the disease is endemic, come in contact with pilgrims from the Near and Middle East and North Africa. When the latter group acquire the infection they give rise to epidemics on returning to their own countries. At present, persons going to Mecca are required to be vaccinated against cholera and when possible, to have negative stool cultures for the vibrio. Large numbers are examined on their return at the end of the pilgrimage, as they pass through government quarantine stations in Egypt, if no vibrios are isolated,

few hours *may* be strongly hemolytic, while after 24 hours the property may be lost, a so journ in artificial media is more prone to change the hemolytic power of "true" vibrios than of El Tor vibrios (Doorenbos, 1936, 1937) Thus, hemolysis is only an approximate guide to the identity of the vibrios, and new criteria would be most desirable in its stead These are being sought e g, lecithinase (Felsenfeld, 1944)

Mode of Transmission

Water is the principal offender, especially when latrines used by infected persons are so situated as to contaminate the water supplies of others Milk contaminated by unclean handling, vegetables contaminated by infected water, dates, and butter, as well as flies (Whitmore, 1929) which may convey vibrios from feces to food, have been mentioned. "Cholera nests," scattered groups of cases infected in such indirect ways, are thus explained Various insecticides such as DDT have been used during epidemics in an effort to eradicate house flies and other insects These may conceivably carry the vibrio (Felsenfeld, 1937) Even direct personal contact if sufficiently close and prolonged (as on board ship), may spread cholera (Whitmore 1929) Cockroaches and rats have been suggested as a method of distribution (Napier 1943) Some writers have expressed confidence in the safety of milk which has soured, since the vibrio does not flourish in an acid medium, but it has been shown that vibrios remain viable in sour milk for as long as 6 days (Whitmore, 1929) Food handlers harboring the vibrio must be thought of also as vectors

Pathogenicity

V comma is known to produce disease naturally only in man. Peritonitis can be produced by intraperitoneal injection of viable organisms into mice, guinea pigs, and some other small laboratory animals, and intravenous injections is fatal to rabbits, but these do not necessarily reveal the route taken by vibrios in clinical infection (Sanarelli, 1916), or even furnish a basis for evaluating vibriocidal drugs

The susceptibility of the host is variable and is obscured by such factors as the number and virulence of the organisms reaching the gut The normal acidity of the gastric juice is thought to destroy most of the vibrios However, the deliberate swallowing of cholera cultures has led to every possible result from noninfection to fulminating disease and death Experience shows that impaired general health, and particularly gastrointestinal disorders, even including the use of a cathartic, predisposes to invasion by cholera vibrios The vibrios may have already been present (carrier state), and become invasive when the patient was malnourished, fatigued, intoxicated, ill with other disease, or, as it has been said, "worried" It may also be impossible to recognize a single predisposing factor in robust persons who acquire and succumb to the disease As with many tropical diseases, the newcomer is said to be more susceptible than the native, and while this may be apparent in other conditions it is difficult to imagine greater susceptibility than that among the natives, say, of India, who perish by the hundreds of thousands

Carrier State

As a rule a cholera carrier either is convalescent after cholera or is in the incubation period of the disease There is rarely a normal or healthy carrier, although low grade or subclinical infections occur Usually, the vibrios do not persist longer than 3 to 5 days after ingestion, either in patients or in carriers Exceptionally they may be present for 2 weeks, and periods as long as 3 and 4 weeks are mentioned It is regularly found (Wilkinson, 1943) that the carrier rate or proportion of subjects examined who show the vibrios, rises to 20 per cent just before an epidemic of cholera In view of incomplete knowledge of the transformation of vibrios from one to another "type," which occurs in the laboratory and also, from statistical data, in the field, it may not be important whether the vibrios are true pathogens Indeed at the outset of the process, they may theoretically be of low virulence, but then one visualizes the transfer of organisms from one host to another, as unsanitary

acterized by whitish shreds of desquamated epithelium ("rice water" stools). Microscopically these shreds contain cells which may be greatly deteriorated or are practically debris and mucus possibly with a few erythrocytes; there is virtually no sign of inflammatory reaction.

The central feature of the disease is the loss of so much body fluid in consequence of diarrhea and vomiting as to produce a state of medical shock (See Table XVI.) This includes hypotension, peripheral vascular collapse,

tissue dehydration and anoxia, acidosis and renal insufficiency. These features almost fully explain the clinical findings in cholera. It may be that the toxin directly damages the kidneys, as shown by albuminuria and casts and at autopsy by congestion and necrosis, but considerable renal damage can equally result from ischemia and the shutting down of glomerular filtration, so that under these circumstances the renal failure is of purely extrarenal origin. It is difficult in fact to identify a feature of the disease that can be attributed to the distribution of a toxin, the one exception being the *sicca* variety of the disease.

Organs Other Than the Intestine

The vibrios make their way, no doubt via the portal system of veins and the lymphatics, to the liver and biliary tract and are often observed in the

the group is declared free of cholera and all are permitted to depart while if vibrios are found, strict quarantine measures are enforced During the past 15 years a new automobile route was authorized for pilgrimages from Baghdad through the heart of Arabia, to Mecca In 1938, Seneca isolated an El Tor vibrio from a Persian pilgrim returning from Mecca through Iraq to Iran

The Egyptian epidemic of 1947 was produced by vibrios introduced by British soldiers proceeding from India to England

The Ganges River is sacred to the Hindus During pilgrimages the devout bathe in the river and the disease acquires epidemic fury It is reported that when the ashes of Mohandas Gandhi were committed to the river this occasioned bathing by a great many persons, which was followed by the occurrence of several hundred cases of cholera

PATHOLOGY

The disease process in cholera begins with the multiplication in the alkaline medium of the small intestine of so many vibrios as have survived passage through the stomach They may barely sustain themselves and no

Fig 156—Intestine in Asiatic cholera showing denudation of the epithelium round cell infiltration edema of the submucosa Low power magnification (×100) (Courtesy of Oscar Felsenfeld) (From Gradwohl Clinical Laboratory Methods and Diagnosis ed 4 1948 The C V Mosby Co)

disease be manifest (carrier state) or they may give rise to mild diarrhea lasting a short time If the infection is massive and virulent and the physical condition of the host unfavorable the intestine is invaded and the full blown disease begins The present belief is that it is the endotoxin released by disintegrating vibrios which is responsible for the destruction of the intestinal epithelium

With injury and desquamation of the epithelium, a serous effusion of prodigious amount pours into the lumen This is passed off as a diarrhea char

sion, but many patients are practically afebrile after the first day or two Often a rise in temperature precedes death, especially with uremia, and then quite high figures are seen We have no reason to believe that elevations were due to pyrogenic infusion fluids, in our time, as they may have been in the past The fact that little or no fever is often seen even when the patient's fluid balance has been restored reasonably well suggests that cholera is not an especially febrile disease, just as Napier (1943) declares Nor is it an especially "toxic" disease, as consideration of the symptoms will show, or a so called toxemia

COURSE OF THE DISEASE

Cholera progresses through well defined clinical stages, provided the patient survives each of them At any stage save that of incubation, he may succumb to the extreme results of fluid loss, but, enduring these, he may yet die of renal insufficiency If the temporary renal shutdown is not fatal, i e, if it does not exceed his tolerance, then recovery will follow and complications are relatively unimportant Uremia is hardly a "complication", it is a completely characteristic feature of cholera and a direct result of the essential disturbance of fluid balance The complications are pneumonia, keratitis (corneal ulcer), cholecystitis, parotitis, jaundice, and abortion

Incubation—This stage may occupy from 1 to 5 days usually 3 days, and may be characterized by vague abdominal distress and infrequently nausea and vomiting, but it is not usually certain that the patient accurately recalls these events It is probable that most patients have no symptoms during this stage If, however, the ingestion of vibrios took place long before the onset which was precipitated by intercurrent disease (e g, dysentery), then the incubation period must have been the duration of the carrier state, or a matter of weeks A very brief incubation period, perhaps only a few hours, is occasionally found during an epidemic, but its significance is difficult to determine

Evacuation—The diarrhea usually begins abruptly and with violence and is soon accompanied by profuse vomiting The stools are passed with a sense of relief, yet the patient is quickly prostrated, with retching, muscular cramps and occasionally hiccup Dehydration becomes obvious within a few hours and signs of circulatory embarrassment, together with *extreme thirst*, rapidly follow Depending on the body resources, evacuation may continue for only a few hours, or intermittently for as long as several days *During this time the picture of extreme shock develops* Exceptionally the onset may be progressive, with only a mild diarrhea and *feculent stools, but even then* within an hour or two, the stage of evacuation is in full course

Collapse—This is the stage of circulatory *failure*, called the "algid" stage, in which the patient lies prostrate, with rapid, weak, and later irregular pulse, distant heart sounds, extreme *hypotension* (*with a* systolic pressure of 60 mm or less, and frequently not determinable) and shallow, rapid respirations *Vomiting and retching cease, although diarrhea may* continue on a

gall bladder If the patient survives long enough this may show injury Organisms have been found in exudates from the lung in patients who later develop pneumonia This has given rise to debate whether septicemia exists particularly since vibrios are rarely detected in the circulating blood (Greig 1913 1914 1915 1916 Nichols 1916)

Post Mortem Findings

Post mortem findings reveal little more than is obvious during life extreme dehydration as reflected in the external appearance general tissues and serous membranes and some reaction about the lymphoid patches of the ileum It is customary to mention also the early rigor mortis and odd positions of the head and extremities When there has been renal involvement the tubules are markedly dilated and the lumen is filled with proteinaceous material there is some interstitial edema but the blood vessels are essentially normal

CLINICAL SYMPTOMS

The symptoms of cholera develop logically from the known disease processes and are peculiar only in respect to their unparalleled intensity What appear a multiplicity of signs and symptoms are the effects of damage to the intestinal mucosa (diarrhea and vomiting) extreme fluid loss medical shock (with the clinical picture of shock generally) and consequent circulatory failure and renal insufficiency (uremia) The origin and character of the several symptoms will be considered in detail

sion but many patients are practically afebrile after the first day or two Often a rise in temperature precedes death especially with uremia and then quite high figures are seen We have no reason to believe that elevations were due to pyrogenic infusion fluids in our time as they may have been in the past The fact that little or no fever is often seen even when the patient s fluid balance has been restored reasonably well suggests that cholera is not an especially febrile disease just as Napier (1943) declares Nor is it an especially toxic disease as consideration of the symptoms will show or a so called toxemia

COURSE OF THE DISEASE

Cholera progresses through well defined clinical stages *provided the* patient survives each of them At any stage save that of incubation he may succumb to the *extreme results of fluid loss but enduring these he may yet* die of renal insufficiency If the temporary renal shutdown is not fatal i e if it does not exceed his tolerance then recovery will follow and complications are relatively unimportant Uremia is hardly a complication it is a completely characteristic feature of cholera and a direct result of the essential disturbance of fluid balance The complications are pneumonia keratitis (corneal ulcer) cholecystitis parotitis jaundice and abortion

Incubation —This stage may occupy from 1 to 5 days usually 3 days and may be characterized by vague abdominal distress and infrequently nausea and vomiting but it is not usually certain that the patient accurately recalls these events It is probable that most patients have no symptoms during this stage If however the ingestion of vibrios took place long before *the onset* which was precipitated by intercurrent disease (e g dysentery) then the incubation period must have been the duration of the *carrier state or a* matter of weeks A very brief incubation period perhaps only a few hours is *occasionally found during an epidemic but its significance* is difficult to determine

Evacuation —*The diarrhea usually begins abruptly* and with violence and is soon accompanied by profuse vomiting The stools are passed with a sense of relief yet the patient is quickly prostrated with retching muscular cramps and occasionally hiccup Dehydration becomes obvious within a few hours and signs of circulatory embarrassment together with extreme thirst rapidly follow Depending on the body resources evacuation may continue for only a few hours or intermittently for as long as several days During this time the picture of extreme shock develops Exceptionally the onset may *be* progressive with only a mild diarrhea and feculent stools but even then within an hour or two the stage of evacuation is in *full* course

Collapse —This is the stage of circulatory failure called the algid stage in which the patient lies prostrate with rapid weak *and* later irregular pulse distant heart sounds extreme hypotension (with a systolic pressure of *60 mm or less and frequently not determinable*) and shallow rapid respirations Vomiting and retching cease although diarrhea may continue on a

diminishing scale There is still no impairment of mental faculties, although some patients begin to have clouding of consciousness and even, in moribund cases, coma The body temperature is likely to be normal, but the skin and even the breath are chilly The patient is an appalling sight, as if already dead, and yet he may live through this stage Anuria may be present

Reaction—Now the peripheral circulation begins to return, and the skin feels warmer Diarrhea has ceased Although oliguria may be present, there is usually some irregular increase in the amount of the urine, with considerable albumin and casts The patient's color improves and the pulse is stronger Bile stained stools may be formed in small amounts, but more often nothing is passed If the patient can produce a liter of urine in 24 hours, it is assumed that recovery will follow

Renal Failure To reach the stage of reaction does not insure recovery This will depend on the re establishment of urinary secretion Even though the circulation returns azotemia may increase with hypertension, delirium convulsions and death in uremia

Sometimes the return of kidney function is intermittent, and finally unsuccessful As in other diseases with renal insufficiency, the blood pressure rises as if to bring about adequate filtration by force, in cholera, this will occur as well as the restored circulation can permit Some nitrogen is thus cleared, but the blood pressure may fall off again, and anuria may return See sawing of this kind may continue, and the patient may die or the quantity of urine may increase progressively albumin become a little less, and azotemia steadily diminish, until an ample flow of urine makes recovery a certainty We have witnessed the latter course during the administration of testosterone (Henderson et al, 1948) when clinical findings suggested irreparable kidney damage From 15 to 25 per cent of the deaths in cholera occur in uremia The proportion is larger in patients with damaged or overburdened kidneys (e g, pregnant women) Any measure which materially aids the restoration of renal function is of great practical value in cholera

The fact that some patients react well, and then go on to uremia has given rise to the supposition that as the circulation improves more toxin can be absorbed from the damaged intestine, and specific injury to the kidney is produced by this toxin On examination it will not be found that any lasting gain in renal function has been established and then lost On the contrary the patient is in renal failure from the stage of collapse, and only intermittently produces a little urine by the mechanism described, before dying eventually of uremia The case for a systemic action of cholera toxin is supported by some other findings but not so well by conditions involving the kidney

Convalescence This is usually rapid but the patient is long in a weakened condition and in early convalescence may collapse as a result of undue effort This is attributed to 'heart failure,' whatever the cause

Manner of Death In severe cases the stage of evacuation passes rapidly into the stage of collapse and with increasing cyanosis and circulatory failure the patient, although conscious, may expire at any time An increasingly

sion but many patients are practically afebrile after the first day or two Often a rise in temperature precedes death especially with uremia and then quite high figures are seen We have no reason to believe that elevations were due to pyrogenic infusion fluids in our time as they may have been in the past The fact that little or no fever is *often seen even when the patient's* fluid balance has been restored reasonably well suggests that cholera is not an especially febrile disease just as Napier (1943) declares Nor is it an especially toxic disease as consideration of the symptoms will show or a so called toxemia

COURSE OF THE DISEASE

Cholera *progresses through well defined clinical stages provided the patient* survives each of them At any stage save that of incubation he may succumb to the extreme results of fluid loss but enduring these he may yet die of renal insufficiency If the temporary renal shutdown is not fatal i e if it does not exceed his tolerance then recovery will follow and complications are relatively unimportant Uremia is hardly a complication' it is a completely characteristic feature of cholera and a direct result of the essential disturbance of fluid balance The *complications are pneumonia* keratitis (corneal ulcer) cholecystitis parotitis jaundice and abortion

COURSE OF THE DISEASE

Cholera progresses through well defined clinical stages provided the patient survives each of them At any stage save that of incubation he may succumb to the *extreme results of fluid loss but enduring these he may yet die* of renal insufficiency If the temporary renal shutdown is not fatal i e if it does not exceed his tolerance then recovery will follow and complications are relatively unimportant Uremia is hardly a complication it is a completely characteristic feature of cholera and a direct result of the essential disturbance of fluid balance The complications are pneumonia keratitis (corneal ulcer) cholecystitis parotitis jaundice and abortion

Incubation —This stage may occupy from 1 to 5 days usually 3 days and may be characterized by vague abdominal distress and infrequently nausea and vomiting but it is not usually certain that the patient accurately recalls these events It is probable that most patients have no symptoms during this stage If however the ingestion of vibrios took place long before the onset which was precipitated by intercurrent disease (e g dysentery) then the incubation period must have been the duration of the *carrier state or a matter of weeks* A very brief incubation period perhaps only a few hours is *occasionally found during an epidemic but its significance* is difficult to determine

Evacuation —*The diarrhea usually begins abruptly* and with violence and is soon accompanied by profuse vomiting The stools are passed with a sense of relief yet the patient is quickly prostrated with retching muscular cramps and occasionally hiccup Dehydration becomes obvious within a few hours and signs of circulatory embarrassment together with extreme thirst rapidly follow Depending on the body resources evacuation may continue for only a few hours or intermittently for as long as several days During this time the picture of extreme shock develops Exceptionally the onset may *be progressive* with only a mild diarrhea and feculent stools but even then within an hour or two the stage of evacuation is in *full* course

Collapse —This is the stage of circulatory failure called the algid stage in which the patient lies prostrate with *rapid weak and later irregular* pulse distant heart sounds extreme hypotension (with a systolic pressure of *60 mm or less and frequently not determinable*) and shallow rapid respirations Vomiting and retching cease although diarrhea may continue on a

diminishing scale There is still no impairment of mental faculties although some patients begin to have clouding of consciousness and even, in moribund cases coma The body temperature is likely to be normal but the skin and even the breath are chilly The patient is an appalling sight, as if already dead and yet he may live through this stage Anuria may be present

Reaction—Now the peripheral circulation begins to return and the skin feels warmer Diarrhea has ceased Although oliguria may be present there is usually some irregular increase in the amount of the urine with considerable albumin and casts The patient s color improves and the pulse is stronger Bile stained stools may be formed in small amounts but more often nothing is passed If the patient can produce a liter of urine in 24 hours, it is assumed that recovery will follow

Renal Failure To reach the stage of reaction does not insure recovery This will depend on the re establishment of urinary secretion Even though the circulation returns azotemia may increase with hypertension delirium convulsions and death in uremia

Sometimes the return of kidney function is intermittent and finally un successful As in other diseases with renal insufficiency the blood pressure rises as if to bring about adequate filtration by force in cholera this will oc cur as well as the restored circulation can permit Some nitrogen is thus cleared but the blood pressure may fall off again and anuria may return See sawing of this kind may continue and the patient may die or the quantity of urine may increase progressively albumin become a little less and azotemia steadily diminish until an ample flow of urine makes recovery a certainty We have witnessed the latter course during the administration of testosterone (Henderson et al 1948) when clinical findings suggested irreparable kidney damage From 15 to 25 per cent of the deaths in cholera occur in uremia The proportion is larger in patients with damaged or overburdened kidneys (e g pregnant women) Any measure which materially aids the restoration of renal function is of great practical value in cholera

The fact that some patients react well and then go on to uremia has given rise to the supposition that as the circulation improves more toxin can be absorbed from the dam aged intestine and specific injury to the kidney is produced by this toxin On examina tion it will not be found that any lasting gain in renal function has been established and then lost On the contrary the patient is in renal failure from the stage of collapse and only intermittently produces a little urine by the mechanism described before dying eventually of uremia The case for a systemic action of cholera toxin is supported by some other findings but not so well by conditions involving the kidney

Convalescence This is usually rapid but the patient is long in a weak ened condition and in early convalescence may collapse as a result of undue effort This is attributed to heart failure whatever the cause

Manner of Death In severe cases the stage of evacuation passes rapidly into the stage of collapse and with increasing cyanosis and circulatory failure the patient although conscious may expire at any time An increasingly

rapid thready and irregular pulse or a leaden complexion with labored shallow respirations ("asphyxial stage") or the advent of coma may portend the loss of the patient

Clinical Varieties Even in a single epidemic all grades of severity can be found The mild somewhat benign diarrheas ("cholerine") are limited to the early cases Patients with this so called choleraic diarrhea may remain ambulatory and never advance to the point of renal insufficiency They serve admirably as carriers

Cholera or "cholera gravis" is otherwise that disease which has been described differing from case to case only in the earliness of death and the predominant clinical features algid asphyctic typhoid uremic etc An interesting clinical variation is found in children where the picture of meningitis is commonly imitated

Cholera sicca (cholera siderans) is a rare form of cholera characterized by sudden collapse and death of a patient before there has even been any diarrhea Post mortem examination shows the presence of rice water containing cholera vibrios in the intestine Because of this perplexing phenomenon it is not possible to rule out a toxin as the cause of profound systemic disturbances in at least a few cases of cholera Whereas cholera sicca is said (Whitmore 1929) to occur in very old or severely debilitated subjects as after dengue or with pulmonary tuberculosis it is not limited to such patients Thus one may reflect on disturbances of salt and water balance severe enough to exceed the functional capacity of the adrenal cortex in any patient whose condition is extremely bad but in the case of robust individuals other explanations must be sought

LABORATORY FINDINGS

Serology

Agglutination produced by the patient's serum begins to appear on the fourth day of the disease in low titer (1 40) and reaches high values at about the seventh day (up to 1 1000) (Pasricha and Chatterjee 1939 Yacob and Chaudri 1945) The "H" antigen produces the more common and marked immune response The response is more or less specific for the infecting strain that is this is better agglutinated than the "standard" organism such as Inaba but exceptions occur Accompanying nonpathogenic vibrios may excite no serologic response whatever Because of the late development of serologic findings they are not of immediate diagnostic usefulness but they have confirmatory value and may be indispensable if vibrios have not been found in the stools *Agglutinins against Brucella* in titers of 1 500 may develop following vaccination against cholera (Eisele et al 1946)

Blood Characteristics

Leucocytosis is present in cholera The sedimentation rate is moderately increased (15 to 35 mm in 1 hour) The features of hemoconcentration are marked specific gravity 1 060 to 1 080 hematocrit 0 47 to 0 82 hemoglobin

diminishing scale There is still no impairment of mental faculties, although some patients begin to have clouding of consciousness and even, in moribund cases, coma The body temperature is likely to be normal, but the skin and even the breath are chilly The patient is an appalling sight, as if already dead, and yet he may live through this stage Anuria may be present

Reaction—Now the peripheral circulation begins to return, and the skin feels warmer Diarrhea has ceased Although oliguria may be present, there is usually some irregular increase in the amount of the urine, with considerable albumin and casts The patient's color improves, and the pulse is stronger Bile stained stools may be formed in small amounts but more often nothing is passed If the patient can produce a liter of urine in 24 hours, it is assumed that recovery will follow

Renal Failure To reach the stage of reaction does not insure recovery This will depend on the re establishment of urinary secretion Even though the circulation returns azotemia may increase, with hypertension, delirium, convulsions, and death in uremia

Sometimes the return of kidney function is intermittent, and finally unsuccessful As in other diseases with renal insufficiency, the blood pressure rises as if to bring about adequate filtration by force, in cholera, this will occur as well as the restored circulation can permit Some nitrogen is thus cleared, but the blood pressure may fall off again, and anuria may return See sawing of this kind may continue, and the patient may die, or the quantity of urine may increase progressively albumin become a little less, and azotemia steadily diminish until an ample flow of urine makes recovery a certainty We have witnessed the latter course during the administration of testosterone (Henderson et al, 1948) when clinical findings suggested irreparable kidney damage From 15 to 25 per cent of the deaths in cholera occur in uremia The proportion is larger in patients with damaged or overburdened kidneys (e g, pregnant women) Any measure which materially aids the restoration of renal function is of great practical value in cholera

The fact that some patients react well, and then go on to uremia has given rise to the supposition that as the circulation improves more toxin can be absorbed from the damaged intestine, and specific injury to the kidney is produced by this toxin On examination it will not be found that any lasting gain in renal function has been established and then lost On the contrary, the patient is in renal failure from the stage of collapse, and only intermittently produces a little urine by the mechanism described, before dying eventually of uremia The case for a systemic action of cholera toxin is supported by some other findings but not so well by conditions involving the kidney

Convalescence This is usually rapid but the patient is long in a weakened condition and in early convalescence may collapse as a result of undue effort This is attributed to "heart failure" whatever the cause

Manner of Death In severe cases, the stage of evacuation passes rapidly into the stage of collapse, and with increasing cyanosis and circulatory failure the patient, although conscious, may expire at any time An increasingly

Depending on the material received, several procedures can be adopted

Abundant specimens can be plated directly on Aronson's medium and *V comma* taken off for agglutination at 18 hours, subculture should be made on plain or alkaline agar, however, to eliminate contaminants The D E C plate or Dieudonné's medium may be used and agglutination tested after 24 hours It is usual to inoculate an alkaline agar plate also directly from the specimen More scanty specimens should be first enriched by culture in alkaline peptone (pH 8 to 9) and vibrios taken off the surface after 4 to 8 hours for further culture Water should be cultured in 0 1 part of peptone with salt (peptone, 10 per cent, and sodium chloride, 5 per cent) for 24 hours in flasks and organisms taken off the surface At appropriate stages, a loopful of material is studied for form and motility

Agglutination Test Taking an organism in pure culture which shows the morphology and motility of *V comma*, agglutination is conclusive evidence of its identity (McLaughlin and Whitmore, 1910) A high titer anti O serum is used in serial dilutions up to 1 500 or 1 1,000 and a loopful taken for a hanging drop preparation Material from a plate colony *is mixed with it, and with an indifferent serum or saline in a control preparation, and the* two preparations compared for agglutination and for loss of motility

Immune serum can be prepared by inoculating a rabbit with a small number, half of a 2 mm loopful, of known *V comma*, suspended in saline and injected intravenously, and bleeding the animal after 8 days Such sera are also commercially available

Macroscopic agglutination (Strong, 1943) is carried out in a test tube, using a loopful of pure agar culture suspended in normal saline, 1 c c, to which is added 1 c c of saline containing the antiserum, and the mixture incubated for 2 hours The mixture is turbid to begin with but if complete agglutination has occurred it is perfectly clear and the organisms are found precipitated at the bottom of the tube Incomplete agglutination is seen as a residual turbidity, with some precipitation Agglutination should be complete at a serum dilution of 1 1000

Pfeiffer's phenomenon is an agglutination test which uses the peritoneal cavity of the guinea pig as the vessel and lysis of the vibrios as an end point It is reliable and rapid the peritoneal fluid being withdrawn after 15 to 20 minutes to determine whether the vibrios are nonmotile and deteriorated, if so, Pfeiffer's phenomenon is present, and the organisms are those for which the serum has activity

Culture of stools for *V comma* is made routinely as follows

1 Inoculate Dunham peptone water, incubate 8 hours
2 Make Gram stain, look for vibrios
3 Streak one of the following and incubate D F C plate, Dieudonné's medium Aronson's medium, alkaline agar plate, or other solid media
4 Isolate suspicious colonies
5 Agglutination with "O" antiserum
6 Hemolysis using 5 per cent sheep or goat cells

If there is no beta type hemolysis *the organism is V comma*, if beta hemolytic it is El Tor type

DIFFERENTIAL DIAGNOSIS

In any epidemic, when bacteriologic proof has been secured for prior cases (see above) an overwhelming gastroenteritis is automatically assumed to be cholera In isolated cases and indeed even in the presence of epidemic cholera it may be necessary to distinguish cases of exceptionally severe shigellosis and of "food poisoning," as well as some more unusual disorders such as malarial diarrhea, meningitis etc Not only is dysentery apt to co exist in cholera country, but there is great likelihood of cholera carriers being precipitated into clinical cholera by an intercurrent shigellosis etc , so that the diseases may co exist in the individual patient Fortunately, energetic treat

85 to 140 per cent erythrocytes up to 8 000 000 (Lebsenfeld 1938) The chemical abnormalities of dehydration acidosis and eventually azotemia are characteristic Blood phenol is reported to be elevated in relation to the severity of the disease The measurement of hemoconcentration can be carried out according to Scudder 1940 (See also Gradwohl 1948)

Bacteriologic Diagnosis

In the Field—With a common microscope and one stain such as carbol fuchsin vibrios can be recognized in the stool

A film composed of mucus shreds from the stool should be dried stained with carbol fuchsin 1 10 dilution dried and examined When cholera vibrios are present they appear as the characteristic comma bacillus and generally have the fish in stream appearance Such an examination does not of course distinguish *V comma* and nonpathogenic vibrios and it should be borne in mind that even in a cholera epidemic almost half the vibrios seen are not pathogens (Heiser 1914 Munson 1915) Identification must be made finally upon a stool sample or peptone water culture or even a tied loop of intestine sent to the laboratory If a high titer anticholera rabbit serum is available then agglutination can be tested with a bit of mucus from the stool (Dunbar 1913) An indifferent serum will not affect the motility of the vibrios while specific serum will cause motility to be lost If a clear difference is found between two specimens treated thus the test has real significance but if negative no conclusions should be drawn since a limited number of true *V comma* might respond to the test but be overlooked among other vibrios The occurrence of nonmotile *V comma* in some epidemics must also be remembered

In the Laboratory (Seneca) —Specimens should be sent with the least delay but if distances are great agar slants can be inoculated in the field and be found useful as long as 2 weeks afterward under tropical conditions (Whitmore 1929) or feces can be suspended in salt solution of 0.5 to 5 per cent strength (Pangamban and Schobl 1918) or in an equal part of bile for preserving the vibrios for several weeks

The laboratory diagnosis of cholera depends on agglutinating with specific serum the vibrios which have been grown in pure culture from a specimen To accomplish this it is necessary to cultivate V comma in a medium which prevents the growth of enteric organisms as well as possible such a medium almost always being very alkaline Prolific invention has been applied to such media which now include besides agar and peptone water Dieudonne alkaline blood agar Panja D E C medium (1943) or Aronson plate (1915) alkaline meat infusion agar (Goldberger 1913) bismuth sodium sulfite broth with brilliant green (Wilson and Blair 1931) or without the dye but buffered to high alkalinity (Read and Pandit 1941 Wilson and Reilly 1940) potassium tellurite (Gohar 1948a) starch egg medium with a striking combination of dyes (Wilson and Reilly 1940) a simple alkaline agar (Volpino 1916) and a great many others (Read et al 1941 Strong 1943) practically all of which serve very well (See Gradwohl 1948) The ideal medium one upon which only cholera vibrios will grow has yet to be discovered

actually under medical supervision about 20 to 30 per cent die the greater number in the stage *of collapse* and the remainder later of uremia but with intensive treatment administered under favorable hospital conditions the mortality may be less than 10 per cent It must be appreciated that patients who live long enough to reach the hospital are necessarily a selected group forming a small proportion of those involved in an epidemic The aged those with renal impairment and pregnant women are especially liable to uremia and as pregnant women usually abort there are the *considerable further risks* of sepsis Children have especially high mortality from cholera

The several clinical manifestations which influence individual prognosis have been mentioned in the clinical section (above)

TREATMENT

An extraordinary variety of supposedly therapeutic measures has come down through the history of cholera and many of these seem difficult to abandon however shadowy the evidence of benefit *More recent contributions* have no better standing even though their logic is more familiar and among these are potassium permanganate (to "oxidize" the "toxin") kaolin (to adsorb the same) and a variety of "disinfectants" With due respect to the honored history of these many objects it should be emphasized that *nothing* should be given the cholera patient *by mouth* unless there is excellent reason to believe it will influence the disease process *This does not however* leave an open field for the hypodermic injection of digitalis epinephrine etc the rationale for which can be debated

Intravenous saline is *the definitive and curative treatment of cholera* It should be given as early as possible and as frequently as necessary to preserve the volume of circulating blood as shown by the hematocrit or blood *specific gravity The blood pressure is a late sign for appraising blood volume* it falls only when no further compensation for a drastically reduced volume is possible and by this time it may be most difficult to restore the circulation even by energetic fluid therapy No rule should be set for the dosage of saline if repeated blood studies are practical the dosage is a *sufficient* amount (Latta 1831 1832) taking 1 060 as the highest permissible blood specific gravity and 50 as the highest hematocrit value If repeated determinations can not be done an empirical dosage of 2 000 c c for adults can be set for the outset of treatment to be repeated every 4 to 6 hours The dosage and interval can be modified according to the amount of fluid loss which is obvious in the individual patient If one administered a large excess *of saline* it would be possible to induce congestive heart failure the signs of which are dilatation of veins in the neck and presacral edema (in a recumbent patient) but as this *is not found during the treatment* of cholera it can be assumed that one is still short of restoring the lost fluid in average epidemic cases Hence the use of saline may be as liberal as desired Only patients with known cardiac pathology or those who pass from dehydration to congestion as a result of treatment call for special caution At the extreme are patients who have so

ment for cholera alone is appropriate to both diseases and in the circumstances of epidemic cholera the differentiation would seem academic

Dysentery due to Shigella or Salmonella may show mucus or blood in the stools but not fluid of the rice water character and there may be abdominal pain or cramps but not generalized muscular cramps involving the extremities anuria is not likely to occur The prolonged diarrhea of salmonellosis when it occurs may be markedly similar to cholera and has given rise to the expression cholera nostras for infections due to *S typhimurium* or *S enteritidis* A conclusive diagnosis must rest on bacteriologic study

Food poisoning can often be traced to its source involves a limited circle of patients and has an incubation period of 12 hours or less unusually short for cholera Knowing the source one might appraise whether it seems a likely medium for transmitting cholera But the clinical picture can be quite as cataclysmic as cholera itself and differentiation on these grounds may not be possible

Botulism is a prostrating disease due to the ingestion of the *Clostridium botulinum* toxin preformed in food It has an incubation period of several days with limited distribution It can be distinguished from cholera by the absence of rice water diarrhea and the development presently of central nervous symptoms (paralysis dysphagia diplopia aphonia)

Malaria prevails in much of the cholera country and may occur in a prostrating diarrheal form The stools are not rice water and the temperature is found high or cyclic A high temperature or splenomegaly should call for quick examination of a blood film and malaria may be found which demands immediate treatment If cholera is known to exist nearby the treatment should be instituted for *both* diseases

Poisoning with mushrooms arsenic mercury etc gives rise to more conspicuous vomiting than diarrhea and generally has a more limited local distribution than cholera If emesis is well established intensive saline therapy should be used on the assumption that cholera might *also* be present if known to be prevalent

PROGNOSIS

No one can accurately assess the absolute mortality due to cholera even within a single epidemic because of the uncertain proportion of the cases which are actually seen and diagnosed Under some conditions there may be one or there may be ten patients of whom no one knows for each one who is treated in part because of the uncertain communications present in the eastern world and in part because of the panic chaos and vast overwork of medical personnel that are present in cholera epidemic areas If therefore one speaks of 50 per cent mortality this includes some patients who have enjoyed medical cognizance and usually some treatment and others who have entered *into local statistics with uncertain accuracy as to both number* and diagnosis It is usually said that the average mortality is 50 per cent

Untreated cases are said to have 40 to 75 per cent mortality Of patients

Some fluid can be given by hypodermoclysis as well This is an auxiliary measure of no consequence in combating acute shock since the uptake of fluid from the tissues is slow at best Intraperitoneal injections are more difficult to give but act rapidly and well (Deb 1947) Finally fluids can be given by rectum if evacuation is not still in progress or has not yet begun (cholera sicca) (Goff and Denney, 1915)

Much emphasis has been given in the past to the use of alkaline infusions—made up with sodium bicarbonate (Rogers 1917) lactate (Banerjee 1936 Banerjee et al 1938 Hartmann 1929 Hartmann and Senn 1932) gluconate etc—in order to combat acidosis (Hartmann 1929 Hartmann and Senn 1932 Rogers 1916 Sellards 1917) It should be remembered that acidosis develops because of renal failure and despite the gratifying results that appear to attend the use of bicarbonate solutions it is not at all clear that correcting acidosis favorably influences renal function In all instances where this was thought to happen ample volumes of fluid had been restored to the general circulation which alone would have regained the acid base controlling function of the kidneys The practical objection to bicarbonate solutions is that they cannot be sterilized without decomposition to the hemolytic sodium carbonate the theoretical objection is that a great proportion of chloride lost from the digestive tract also needs to be replaced (Banerjee 1941) That sodium chloride can be given in excess does not seem likely

The custom of designating one type of infusion as most suitable for the stage of evacuation another for collapse still another if uremia threatens one especially adapted for controlling shock etc appears to ignore the single underlying disorder that gives rise to these successive manifestations It may be remarked that a sudden accession of fluid may be poorly handled by patients in collapse hence the first infusion must be administered slowly and with close observation and with particular notice of the temperature of the fluid When the response to saline infusions is limited it must be recalled that the advanced stages of diarrhea entail a loss of protein as well which can be made up by adding human plasma to the infusion if it is available There are otherwise no necessary departures from the intensive use of saline infusions as the central treatment of cholera

Sulfonamides—Since in any cholera epidemic up to 100 per cent of untreated patients will die while more than 90 per cent of patients treated with saline will survive it is difficult to appraise the effect of treatment directed against the vibrio itself It should also be remembered that the organism does not survive more than 3 to 5 days even if no drug is used so that treatment must have effect in the earliest course of the disease if it is to accomplish anything of use later it can only add to the embarrassment of the kidneys

Thus far there have been reports of the use of sulfaguanidine (Chopra et al 1941 Chu et al 1946 Gupta et al 1945, Huang 1944 Indian Research Fund Association Report 1943 1944 1946 Seal 1947), succinyl sulfathiazole (Indian Research Fund Association Report 1946), sulfadiazine

little remaining blood that the veins when cut down for instilling the infusion do not even bleed in such cases the requirement for fluid is so great that it may never be satisfied far less exceeded

The saline to be administered should ordinarily be physiologic salt solution 0 85 per cent NaCl pyrogen free in distilled water Hypertonic saline (13 75 Gm NaCl 0 25 Gm $CaCl_2$ per liter) is advised in "more severe" cases in fact it is difficult to distinguish which cholera patients are less severe than others or to show that one solution has served better than the other The same is true of improved solutions containing for example 5 per cent glucose (Gaertner 1915) These supply a modicum of nutrition (200 calories per liter!) which is of undoubted aid In actual practice one employs the materials at hand Even distilled water has been employed with apparent benefit (Sen Gupta 1945)

If there is actually any choice of solutions new information inclines one to the choice of a potassium containing infusion such as Rogers hypertonic mixture of NaCl 8 Gm $CaCl_2$ 0 25 Gm and KCl 0 4 Gm for the following reasons (1) As the patient recovers water is regained more quickly than electrolyte leaving the patient in a state analogous to salt depletion or water intoxication even though this fact is not apparent on clinical grounds Nominally at least an excess of salt is desirable from the time of collapse (2) Data from the treatment of infantile diarrheas in which fluid loss reaches somewhat the magnitude found in cholera suggest that one effect of a loss of extracellular fluid is movement of intracellular fluid outward to take its place in some measure As the latter contains primarily potassium there is a depletion of tissue potassium stores not remedied by the usual sodium salt infusions and adding subsequently to the general electrolyte derangement and systemic weakness Infusions providing a small proportion of potassium salts have in infants yielded considerably better results as judged clinically It is our belief that the same rationale applies in cholera As has been mentioned however it is not possible to distinguish on either clinical or statistical grounds whether one or another solution is the more appropriate hence the recommendation must be made on the basis of physiologic theory rather than conclusive experience

The solution should be warmed preferably to higher than the body temperature before administering Any convenient container partially filled with warm water and if possible surrounded by an insulating jacket for night or cold weather can be used to suspend the infusion bottle and keep its contents warm Whether an excessively warm infusion dilates the peripheral vessels and nullifies its own effectiveness in fitting the blood volume to the vascular bed may be disputed but certainly the temperature at the needle should never be less than 99° F and it ought to be 2 or [illegible] degrees higher in any except febrile patients The possibility of adjusting each patient's infusion to his body temperature at the time however attractive in theory is remote under the usual conditions of epidemic cholera

kaolin (Arneth, 1916, Kuhne, 1918), essential oils alcohol, atropine, irrigations of the stomach, acids by mouth, coffee to aid the kidneys, digitalis to aid the heart, Adrenalin, cupping, hot packs mustard plasters etc More recently we hear of bacteriophage (Jadin 1936, Pasricha, 1942, Sen and Basu 1945), antitoxic serum, antivibrio serum, drugs such as Atabrine (Panja 1945), dyes such as brilliant green (Panja and Ghosh, 1943), antibiotics such as streptomycin (Reimann et al, 1946), etc *It is seldom reported that any of these measures has failed to produce marked benefit in a goodly series of cases especially since all are treated with saline infusions and have an excellent chance to recover for that reason*

The use of chloramphenicol (Chloromycetin) in experimental cholera infection has been reported by Gauld et al (1949) Gauld and fellow workers attempted to determine the activity of this drug against *V comma* both in *vitro and in the treatment of mice experimentally inoculated with this organism* Chloromycetin was tested for its inhibitory effect upon two strains of *V comma cultured in single strength brain heart infusion broth with a pH of* 7 6 Complete inhibition of growth was obtained with 0 005 mg of Chloromycetin per cubic centimeter of culture media *In vivo experiments* were made with Chloromycetin Each experiment included groups of mice that were inoculated with *V comma* and treated with sulfadiazine Cultures of the Inaba and the Ogawa strains of *V comma* on veal infusion broth were used to induce the experimental disease in mice In each instance 0 5 c c of inoculum suspended in 5 per cent hog gastric mucin was injected intraperitoneally While it is not possible to reproduce the human disease in laboratory animals the *intraperitoneal injection of large doses of V comma* into mice causes a rapidly developing septicemia and peritonitis lacking however, the vomiting diarrhea and extreme dehydration characteristic of cholera in man The *important conclusions* from this work were that Chloromycetin is an effective antibiotic for the treatment of mice experimentally *inoculated with V comma,* when given in adequate doses between 1 hour before and 2 hours after the injection of the *organisms These experiments suggest* the possible usefulness of the drug as a chemoprophylactic agent among human contacts of cholera

Editor's note (O T) *Recently* bacitracin, neomycin and terramycin have proved useful in experimental cholera

Testosterone—We (*Henderson et al* 1948) have administered large doses of testosterone propionate to cholera patients who were in uremia less as a therapeutic measure than as a study in experimental medicine, the object being to utilize the restorative function known to be exerted upon the injured kidney by androgenic hormones (The supporting data, being rather extensive, are presented in full in our report) The resulting *decline in* mortality was sufficiently obvious to confer a therapeutic status to the experiment In 27 *uremic* patients the mortality was *less than 20 per cent* as compared with 70 per cent usually found under the same circumstances in the same epidemic We employed 25 or *50 mg testosterone* propionate daily by intramuscular injection, an essentially arbitrary amount, there is no objection

(Chu and Huang 1946, and Chu et al, 1946 Indian Research Fund Association Report Reimann et al, 1946), a modified sulfathiazole (Bhatnagar et al, 1948) and various other sulfonamides (Lehiri 1945, Pasricha 1942, Sadusk and Oswald 1946, Sen and Basu, 1945) Only one drastic experiment (Indian Research Fund Association Report 1946) used the drug without saline, in 53 cases, with a mortality of 21 per cent compared with 75 per cent in 44 control patients This certainly furnishes proof of the theoretical value of anti infective therapy, but its practical significance must be doubted since any patient receiving medical attention at all can equally well receive saline, when the mortality is even lower The difference produced by sulfonamides among saline treated patients is less manifest with sulfaguanidine the mortality is reduced from 6 to 2 per cent (Indian Research Fund Association Report 1946) or from 5 to 1 per cent (Gupta et al 1945) or in a smaller series from 39 to 17 per cent (Indian Research Fund Association Report 1946) with sulfadiazine from 10 to 0 per cent (Chu and Huang 1946) Thus taking all the experience together, it can be said that the best modern treatment is apt to produce a mortality of 6 per cent while the further addition of sulfonamides will reduce this to only 3 per cent (Seneca and Henderson) Yet the inclusion of a few more or less favorable cases in a series or the difference of a day's time in starting treatment may lead adventitiously to greater contrasts than this

A choice of sulfonamides is easily made All who have tropical experience look with dread upon compounds like sulfadiazine an absorbable sulfonamide having a likelihood to precipitate in the kidney if the patient is at all dehydrated (and even if he is not) Regardless of its activity against the cholera vibrio sulfadiazine is not a drug of choice in the tropics, and very particularly not in the fluid depletion of cholera Instead one should elect one of the nonsystemic or unabsorbable" compounds In view of irregularities of its behavior sulfaguanidine is not an ideal member of this class The choice lies between succinylsulfathiazole and phthalyl sulfacetimide and of these phthalyl sulfacetimide is known to have not only excellent vibriocidal power but a striking ability to become absorbed into the proper tissue of the intestine—rather than so to speak accumulate within the lumen where it can affect the free noninvading organisms only Our own experience (Seneca and Henderson) in a preliminary series of 40 cases was quite satisfactory Only one patient was lost and no toxic action of any kind could be attributed to phthalyl sulfacetimide If therefore the means are at hand to supplement the established fluid therapy of cholera with sulfonamides the use of phthalyl sulfacetimide is especially to be recommended Failing this succinylsulfathiazole should be of some value Other compounds including some recent innovations for which the evidence is unimpressive are better dispensed with rather than add further injury with doubtful benefit

Other Methods—It would be tedious to enumerate the preparations which have no recognizable value in cholera but enjoy earnest support in various parts of the world From olden times we have purgatives permanganate

must be suspected. Water in wells can be treated according to the local fashion with either potassium permanganate or calcium hypochlorite in order to produce a residual chlorine content of 2 ppm or higher. (Convenient testing devices can be used to show whether the residue is sufficient. If the taste is obnoxious the water can be allowed to stand for a day if protected from contamination or a little ammonia can be added before chlorination.) Since there is not universal agreement upon the security given by these measures it is likely that more water will be boiled as the epidemic becomes more oppressive. The inclination toward tea drinking in cholera country has probably saved countless European lives.

Contaminated water can be found on the hands as well as the food, especially if one is dealing with cholera patients. Personal cleanliness is urgently needed.

In the presence of an actual case of cholera, continuous disinfection of the patient's dejecta and of linen and other articles in contact with the patient must be carried out. There must be no opportunity for patients or carriers to contaminate the water supplies (or food) with their feces. Flies must be dealt with by screening and by insecticide sprays used indoors, and their bodies must be treated as infected material.

Most of these efforts are self evident. One must have full cognizance of the infectious material discharged by patients and carriers and where it goes. One must have full knowledge of what comes into the mouth and where it comes from. Trained personnel are aware of both, indifferent native personnel may pay little attention to either.

On a more than local scale the importation of cholera into a new region or country can be guarded against by quarantine, a delay allowing incubating cholera to become manifest (Smith 1938), but carriers can be detected only by repeated stool examinations and remain an important hazard. It is said (Strong 1943), however, that epidemic cholera has not been transmitted by a carrier of more than 2 months standing. Air travel has introduced a new complexity, since the incubation period of cholera may not elapse en route as it necessarily does in sea travel, and thus rules have been placed in effect to delay the arrival of persons from cholera country until incubation can be completed. In the end, of course, the control of the disease depends above all upon the security of water supplies in the country of arrival. That this is never perfect has been vividly shown, for example, by amebiasis in Chicago, and may at any time become apparent again.

Immunization.—The use of vibrio material as an inoculation material was introduced as early as 1885 by Ferran, who employed living organisms injected subcutaneously. At present a variety of methods is used to prepare vaccine (Jennings and Linton 1944, Pandit 1948, Ranta and Dolman 1943, Sokhey 1944) and various tests such as the guinea pig (Sugino 1935) and mouse protection tests (appraising the antibodies developed in the human subject's serum) are carried out in the effort to evaluate the materials used (Ciuca and Balteanu, 1926, Griffitts 1944, Ranta and Dolman 1944). In

to much larger doses Our impression was that renal function was more rapidly (and more usually) restored in the treated patients, and in typical cases it was possible to trace a relationship between the treatment and this effect although only an extended series could show this conclusively Not a large number of cholera patients nowdays die in uremia but of deaths in cholera uremia is responsible for a very large proportion. We have felt that our experiment should be continued wherever the circumstances permit While the beneficial effect of testosterone is mainly related to kidney function it should not be overlooked that it also produces sodium chloride and water retention which is probably responsible for part of the physiologic benefit It is known that the adrenocortical hormone administered as desoxycorticosterone acetate has even more marked action and aids in maintaining the blood pressure under adverse conditions of water balance It might well be found that both hormones can be used to advantage prophylactically if the opportunity is presented rather than permit uremia to develop Moreover when utilized sufficiently long in advance of collapse the use of testosterone may contribute greatly to improved nitrogen balance

General Management—The cholera patient should be put at rest and disturbed as little as possible Morphine should be administered to relieve anxiety restlessness and muscular cramps the dosage should not be calculated to reduce the diarrhea as this is futile No food can usually be given by mouth as it will be vomited immediately Every effort should be made to induce the patient to take fluids by mouth Many cannot take fluids but one must keep trying to get fluids into these patients Where water or fruit juice cannot be tolerated try shaved ice a spoonful at a time or better still shaved ice with ginger ale Some control of the vomiting can be secured with small doses of cocaine such as 8 mg ($\frac{1}{8}$ gr) and it may be advantageous to administer this dropwise under the tongue in smaller amounts Intravenous fluids should be started as soon as the diagnosis is made and should be continued If phthalyl sulfacetimide is available 5 Gm should be given as early as possible then 1 Gm every 2 hours for 5 days by mouth

When the stage of collapse is reached other medication should be withheld but the infusions maintained perhaps with the addition of glucose 5 per cent and thiamine (2 mg per liter of glucose solution) Glycosuria can be ignored If testosterone propionate is used it can be begun at any time but preferably before renal insufficiency is advanced unless one is making a deliberate selection of cases and at least 50 mg should be administered daily

PROPHYLAXIS

Control of Transmission—When cholera is known to exist in a region utmost attention must be paid to the sterilization of water—not only drinking water which can be observed and controlled but also the water which contaminates vegetables sea food etc For this reason eating uncooked food is dangerous Even fruits before being peeled should be washed clean in boiled water or steeped in boiling water Ice and all contents of an ice refrigerator

health activity in China It would be a happy and novel event if the cholera vibrio, transmitted as freely as before, never found a human intestine in which it could survive and multiply

ulations are usually subcutaneous (but they may also be intradermal—nja and Das, 1947) and consist of 8 000 million killed *V comma* per cubic timeter, the dosage being 0 5, 0 5, and 1 0 c c at intervals of 7 to 10 days various criteria, the induced immunity is short, lasting only 6 months or less, that reinjection of 1 c c is practiced every 4 months in the presence of demic cholera While the older literature contains a diversity of opinion to the effectiveness of vaccination, and indeed it might be impossible to show clusively that it is effective, experience strongly favors it In India, for ample cholera is ten times as common among unvaccinated as among vaccinated persons, using either a phenolized or a "protein free" material (Pandit 18, Sokhey, 1944) A similar reduction of morbidity was reported in the eek army (Arnaud, 1914) and in other armies (Kersten, 1918) The Nizam Hyderabad forbade pilgrims to cross his territory unless they were vaccinated ainst cholera when it was found that the disease was practically eradicated m their groups (*palkies*) even though it had been present when they started ao, 1947) Though morbidity may occur even with vaccination, the mortality demonstrably smaller We did not see patients with cholera who had been en complete vaccination 3 weeks or more previously while those who had en inoculated more recently were indistinguishable from other patients is not necessary to use a vaccine prepared from numerous strains of cholera brio The Ogawa and Inaba types should be present and recently isolated ains probably have greater protective value than stock organisms

Recently a cholera toxoid obtained from El Tor vibrios (Gohar, 1948c, kita 1939), has been employed, it has been combined with killed vibrios d administered simultaneously with vaccine of dysentery bacilli a rational d desirable combination (Felsenfeld and Young 1945)

Despite the probable value of vaccination, the most important factor to otect against cholera is general and personal hygiene

Chemoprophylaxis—Bacterial inoculation, while statistically effective, sures variable protection to the individual and then only after a delay of veral weeks. It is evident that greater security can be secured for persons ose to an actual epidemic This has been attempted by giving prophylactic ses of sulfadiazine (Peterson 1946), but it is our belief that a less toxic lfonamide is desirable for routine use in large groups of people We have licated (Seneca and Henderson) that such a compound as phthalyl lfacetimide can be used for this purpose It is applicable to routine adminis ation on a large scale without immediate supervision since no detectable ood concentration is set up and there is no conceivable hazard of crystalluria ontrolled groups such as military personnel or hospital staffs exposed to olera in a region can be afforded continuous protection from the first day a standardized prophylactic dose such as 1 Gm daily Whether such a nple measure will ever find province or nation wide application, as in India, problematic although the far more troublesome vaccination has been extended groups as exten

CHAPTER 29

SALMONELLOSIS—SHIGELLOSIS

Oscar Felsenfeld and Viola Mae Young

SALMONELLOSIS

(Typhoid and Paratyphoid, Salmonella Infections, Enteric Fever)

DEFINITION

Salmonellosis is a disease or carrier state caused by bacteria belonging to the genus Salmonella

ETIOLOGY

The members of the genus Salmonella are usually characterized as gram negative non spore forming, mostly motile aerobic and facultative anaerobic microorganisms which ferment dextrose and mannitol with the formation of acid and gas (with the exception of the typhoid bacillus, the fowl cholera organism and a few so-called anaerogenic strains which produce acid only but no gas) do not ferment sucrose lactose or salicin do not form indole or acetylmethylcarbinol and which have a serologic pattern which fits into the White Kauffmann Edwards schema All Salmonellae are pathogenic for man and animals

The genus was named for Salmon who first described an organism belonging to this group (*S choleraesuis*) Some bacteria previously placed into different genera have now been definitely added to the Salmonella group the typhoid bacillus (*S typhi* or *S typhosa*) and the fowl cholera organism (*S gallinarum*) Some difficulties have been experienced with the nomenclature of Salmonellae

In spite of the efforts of the Salmonella centers obsolete and unaccepted nomenclature is frequently used Table XVII shows the most frequently used terms

The isolation of Salmonellae is described in Chapter 71 Here we wish only to reemphasize that the exact diagnosis of the type is a task which must be carried out in specially equipped laboratories, called Salmonella centers It is recommended however that the local laboratory test the basic biological properties of every organism suspected of being a Salmonella eventually perform an agglutination test with a polyvalent serum and report to the physician "Salmonella present Type to follow"

Details regarding the typing of Salmonellae are contained in the publications of Kauffmann (1941) Edwards and Bruner (1943 Monteverde (1943) Felsenfeld (1947) and Cruickshank (1948)

About 150 types and varieties of Salmonella are known to date While any of them might be encountered in a given case or outbreak of salmonellosis but 15 strains comprise the majority of types isolated from man

EPIDEMIOLOGY

To Hormaeche et al (1940) belongs credit for the so called "Montevideo Doctrine" which asserts that persons contracting Salmonella infections react

In America where large quantities of fowl and eggs are consum Salmonellae which occur in fowl are frequently found in human salmonello Hinshaw et al (1944) and Kessel et al (1945) first emphasized this fact T meat of poultry, eggs, and egg products may carry the infection

Meat of hogs and cows very often contain Salmonellae Rubin et (1942), Cherry et al (1943), Hormaeche et al (1940), and others have fou Salmonellae even in the best, federally inspected market meat Brain lym nodes, and liver seem to be the most frequent sites of Salmonellae in anim The animals may be symptomless carriers

Rodents frequently harbor Salmonellae without dying of the infectio Rats and mice may contaminate stored food with their droppings and th transmit the infectious agent to man

Flies are recognized vectors of salmonellosis They carry the organis passively on their wings or legs also in stool particles

Certain foods provide an excellent medium for the growth of Salmonell Nearly all milk and egg products as cream, mayonnaise and ice cream a capable of supporting multiplication or survival of these organisms S monellae survive on vegetables kept in the icebox for many weeks (Felsenfe and Young 1945)

The duration of the carrier state is variable Rubinstein et al (194 found that about 2 per cent of all persons infected with Salmonellae excre these organisms for a period longer than 1 year

For the enumeration of the sources of infection and carrier state, refe ence is made to the articles of Bornstein (1943), Felsenfeld (1945), a Gradwohl (1948) Only the epidemiology and distribution of the most co mon Salmonella strains will be discussed in this chapter

S typhosa the typhoid bacillus, causes only human infection mostly in the form typhoid fever The organism is transferred from man to man chiefly by carriers who act food handlers, and by polluted water It occurs throughout the world but is a particula serious problem in neglected rural communities with little or no sewage disposal or food a water sanitation The average mortality is 8 per cent Many epidemics of typhoid fever m be traced with the aid of bacteriophage typing of the causative organism According to t phage susceptibility, several subtypes of *S typhosa* are known

S paratyphi A predominates in subtropical and tropical regions It is also present continental Europe This infection follows the typical man to man pattern It is natur that food and water soiled with excreta of both active cases and of carriers play an emine role in the communication of paratyphoid A infections

S paratyphi B causes about 20 per cent of the salmonellosis cases in America. It usually communicated by man but has frequently been recovered from pigs, cows, sheep, a rats, chiefly in South America It is present all over the world, being superseded, howeve in some areas by the more numerous paratyphoid A infections *

S paratyphi C is practically unknown in America but it is frequent in the Near Ea India, and Netherlands Indies Its epidemiology resembles that of *S paratyphi A*

S typhimurium is the most common Salmonella, causing about 30 to 35 per cent of a Salmonella infections It usually produces an enteritis of a few days' duration *S typh*

*In recent years *S paratyphi B* has been encountered less frequently

in different manners depending on several factors among which age and general health play a great role Thus septicemia and meningitis are more frequent in young animals and in infants than in healthy adults Similarly higher mortality is observed in debilitated people The strain of the organism is of lesser importance for the course of the disease This doctrine has been generally accepted chiefly after statistical proof by Edwards and Bruner (1943) Pornstein (1943) Seligmann et al (1946), and Hinshaw et al (1944) invalidated the Kieler Doctrine ' which gave credit only to the strain of Salmonella in the determination of the course of the infection

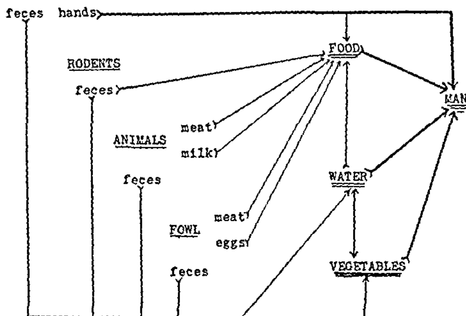

Fig 158.—The transmission of Salmonella

Certain Salmonellae as *S typhosa S paratyphi* A and C are mostly transferred from man to man Patients during the actual illness are not such dangerous sources of infection as are symptomless carriers Salmonellae transmitted from man to man are most frequently transferred by dejecta which adhere to the fingers of food handlers and by drinking water which has been soiled with fecal material The supervision of food handlers including dairy workers is an important measure for the prevention of salmonellosis The story of Typhoid Mary is so well known that it need not be repeated here Not only *are those Salmonellae which like the typhoid bacillus are common to man but* not animals propagated by food handlers but other Salmonellae are also frequently spread by human beings

The Classical Enteric Fever

In most instances classical enteric fever is a separate well defined clinical entity with typical pathologic findings It is described in more detail in Chapter 30

Classical enteric fever is a disease of the lymphatic tissues of the intestine spleen and bone marrow and is characterized by the invasion of these organs by large mononuclear phagocytes also called ' typhoid cells ' The initial hyperplasia may dissolve through resorption or focal necrosis may develop chiefly when vascular occlusions caused by bacterial emboli enter into the picture

The invasion by large mononuclears causes hyperplasia of the Peyer s patches and solitary lymph follicles These lymphatic structures become enlarged and project above the surface of the intestine The changes are most evident in the lower part of the ileum and are difficult to follow in the large intestine because of the less extensive lymph follicles in that part of the bowel. After swelling necrosis follows Round oval or elongated ulcers result which due to the topography of the Peyer's patches extend along the longitudinal axis of the intestine When only a part of the lymphatic structure necrotizes irregular ulcers result

The ulcers have a relatively clean floor They reach into the muscularis but may be so deep that they extend to the peritoneum Edema is usually observed in the environment of the ulcers

These changes either are resorbed or they heal practically without any scar formation Perforations develop in certain instances

The abdominal lymphatics are congested and enlarged due to the invasion by large mononuclears The spleen is acutely congested and enlarged it is deep red and soft The sinuses are distended There are many red blood cells in the pulp Large mononuclear cells are very numerous small areas of necrosis are not infrequent The bone marrow shows many large mononuclear cells and necrotic foci The liver is large swollen and cloudy There is a proliferation of the mononuclear cells and focal necrosis usually causing small lesions The gall bladder shows only slight inflammation as a rule The kidneys do not reveal much pathology cloudy swelling is often observed.

The heart muscle may suffer degenerative changes brown atrophy is frequently observed in fatal cases The femoral and saphenous veins and the cerebral sinuses are often thrombosed The lungs may suffer from pneumotyphoid caused by Salmonellae in which typical organisms are isolated from the sputum Secondary bronchitis and bronchopneumonia seem to be more frequent than the lobular typhoid pneumonia

The bones chiefly the tibia sternum ribs and spine may be the seats of chronic suppurative lesions The rose spots of the skin are caused by bacillary emboli of the capillaries

It is self evident that the quantity and extension of these lesions may vary from case to case

murium is spread by man, hogs rodents, cows, and fowl *Human carriers, meat of infected animals and fowl, eggs, and food contaminated by rodents are the chief sources of human disease*

S choleraesuis occurs throughout the world Most infections are observed in America, England and the Pacific area Pork is the principal source of infection Human carriers are extremely rare This organism is the most dangerous of the Salmonellae, causing septicemia, with a mortality of about 25 per cent

S derby is found *under* all climes but attains local importance only in America The *chief sources* of infection are man fowl and hogs Sick poultry *seems to* play the greatest role *S derby* usually causes only enteritis

S thompson is rare in America but *frequent* in Europe where it attacks man and *poultry* Few cases have been reported from the tropics Most infections originate from eggs

S montevideo is found most *frequently in* the New World and in the Mediterranean area Man, fowl and hogs harbor this organism In human beings *enteritis is* the most common clinical manifestation

S oranienburg occurs more *frequently* in *Europe* than does *S montevideo* It has the same epidemiologic features

S newport has a world wide distribution acquiring much local importance *in* the warmer parts of America, in India, and in the Pacific area Man poultry, and hogs are the principal sources of infection *The* disease appears under various clinical pictures of salmonellosis

S enteritidis is a major cause of salmonellosis in *Europe India* and the Pacific area but is only a minor agent in America *being infrequent* in American fowl

S dublin is practically unknown in North America but is very often encountered *in* South America South Africa Australia, and England It is endemic *in cattle S dublin* infection of ducks in Denmark is the probable cause of *its frequency* in human beings in that *country*

S panama is a typical organism of the New World It is often isolated from man poultry and pigs causing in *human beings* every clinical form of salmonellosis

S anatum is frequent in America the Mediterranean area and Netherlands Indies It is readily isolated from man poultry and hogs *The* disease usually caused by *S anatum* is enteritis

Other Salmonellae, which are more unusual may attain local importance *but these are of less frequency* The strains enumerated above cause 90 per cent of the world s Salmonella infections To complete the list the following Salmonellae may be mentioned

S saint paul, S reading S abortusbovis *S* bredeney *S* bareilly *S hartford S tennessee, S muenchen S berta S* sendai *S* pullorum *S gallinarum S london S give, S meleagridis S* newington *S new brunswick S senftenberg S pretoria S worthington, S kentucky S minnesota* and *S urbana*

Because *of the* infrequent occurrence of these Salmonellae any statement regarding their means of communication would be merely theorizing without adequate foundation

PATHOLOGY

The post mortem findings differ in most cases according to the clinical form of salmonellosis Deviations from this rule however are frequent Extensive changes with few clinical symptoms and vice versa, are by no means rare exceptions There is little connection between the causative organism and the pathologic changes except in a few instances such as in the classic picture presented by typhoid fever *S choleraesuis* infections etc In the following paragraphs the classification of salmonellosis according to Hormaeche et al (1940) is followed with regard to Manson Bahr s (1945) observations

stood however that salmonellosis may cause a true appendicitis but the pseudoappendiceal picture is more frequent

Hormaeche et al (1940) divide Salmonella gastroenteritis in children into a dysenteric and a choleriform group The pathologic findings however are only exceptionally characteristic There may be hyperemia and inflammation If ulceration is present the ulcers are very often small In many cases they are limited to the large intestine In some cases an acute gastritis is present (Angrist and Mollow 1946) Sometimes the lesions reach the rectosigmoid and resemble bacillary dysentery

The lesions heal without scar formation or give rise to sequelae such as mucous colitis irritable colon " or ulcerative colitis

Pseudosurgical Syndrome

Pseudosurgical syndrome is a clinical picture rather than a pathologic entity It was most extensively studied by Seligmann et al (1944 1946) Salmonella enteritis may appear under the clinical picture of appendicitis cholecystitis or inflammations of the female genital organs The pathologic changes are rarely typical and the diagnosis is made by laboratory examinations

Carrier State

Persons who excrete Salmonellae without being actually ill are called Salmonella carriers Such a state may develop after an attack of salmonellosis and the patient is then called a ' convalescent carrier ' The contact carrier acquired his infection during an outbreak without becoming sick The chronic carrier excretes Salmonellae for a considerable length of time e g for more than one year The active carrier harbors the organisms in his intestinal canal while the 'passive carrier discharges them only during the period of ingestion

The most outstanding pathologic changes are found in chronic carriers The gall bladder usually shows only a slight inflammation in enteric fever In most carriers however the gall bladder contains numerous lymphatic nests and infiltrates Whether Salmonellae can predispose to the formation of gall stones or whether gall stones favor the settlement of Salmonellae is open to discussion Extirpation of the gall bladder has cured numerous carriers this practice is much recommended by many authorities

CLINICAL SYMPTOMS

The clinical symptoms as related to statistics on the occurrence of Salmonellae are discussed by Edwards and Bruner (1943) Rubinstein et al (1944) Seligmann et al (1946) Varela and Zozaya from Mexico (1942) Vaccaro et al from Chile (1943) Kitching from Canada (1945) Bruner (1945) and Maccolini (1941) from the Mediterranean area Hayes and Freeman from India (1945) Lindberg and Bayliss from the Pacific area (1946) they are described in the survey articles of Hormaeche et al (1940), Bornstein

Typhoid Like Fever (Salmonella Fever)

As stated before although any Salmonella may cause this symptom complex, the principal agents are the paratyphoid bacilli *S sendai*, *S panama*, and others The pathology has been much discussed Recent contributions, such as that of Angrist and Mollov (1946) shed much light upon the pathology of this form of salmonellosis

Autopsy findings in Salmonella fever show wide variations The picture of classical typhoid (enteric) fever is not infrequent in fatal cases More often however specific post mortem changes are lacking Little or no pathology is present in the lymphatic tissues Inflammation may dominate the picture, without much hyperplasia The participation of organs other than the intestine may be less than in the classical enteric fever The lungs and bones are rarely affected Venous thrombi are only exceptionally found Perforations are infrequent The spleen is not always enlarged Emboli of the skin capillaries are rare except in paratyphoid B fever The gall bladder is often attacked

Septicemia

There is a bacteriemia in all cases of classical enteric fever and in Salmonella fever A separate clinical entity called Salmonella septicemia includes a symptom complex in which the septic high remittent fever predominates Little or no changes are found in the intestines If such alterations are present they may be typhoidal in nature or only a nonspecific inflammation is seen When the case is examined at autopsy the initial intestinal disturbances which frequently introduce Salmonella septicemia are already healed in the great majority of fatalities Frequently however the infection enters the blood stream through the tonsils without passing through the intestines In such instances the participation of the intestinal lymphatic apparatus is not necessarily greater than that of the other parts of the body Bronchitis and bronchopneumonia are the most frequent collateral findings

Salmonella septicemia may lead to diseases of various organs Meningitis parametritis cholecystitis endocarditis pneumonia pyelitis nephritis and osteomyelitis are the most frequent forms of inflammation and abscess formation Meningitis and osteomyelitis are more common in infants while pneumonia pyelonephritis and cholecystitis occur more frequently in old people

Salmonella septicemia seems to be far more common in young children and in persons suffering from other diseases—arteriosclerosis, diabetes nephritis and leucemia—than in healthy adults Thus the autopsy findings are obscured by the pathology which must be attributed to the wasting disease which lowered the resistance of the patient to such an extent that the development of the septicemia became possible

Enteritis

Salmonella enteritis (or gastroenteritis) rarely is a direct cause of death Death is somewhat more frequently observed when salmonellosis causes a pseudoappendiceal syndrome upon which surgery is performed It is under-

Headache malaise insomnia apathy and dizziness are regular features of the picture Pain in the back and in the limbs is often reported Anorexia is usually present stupor develops in about 75 per cent and delirium in about 30 per cent of the cases Psychosis is rare

While a stiff neck is present in about 10 per cent of the patients meningismus and meningitis are not very frequent These must be differentiated by cerebrospinal fluid examination

The tongue is coated its margins are often clean thus presenting the picture of the typhoid V The mouth is dry and thirst is a frequent complaint The cheeks are flushed giving the patient the well known facies typhica

An early symptom is epistaxis which is observed in about 25 per cent of the patients Respiratory catarrhs are very frequent being present in about 50 per cent of the cases The number of cases with bronchitis increases during the later course of the disease While coryza is very frequent bronchitis develops in about 75 per cent pneumonia in about 10 per cent of the cases Bronchopneumonia and pneumonia usually develop during the third week or later

The pulse is slow principally before the temperature reaches its maximum The pulse rate is slower than one would expect from the temperature rarely exceeding 96 to 120 per minute at 103° to 105° F A dicrotic pulse is present in about 40 per cent of the patients This dicrotism is mostly observed during the second and third week of the disease The blood pressure is usually low A soft systolic blowing sound is present in about 30 per cent of the cases it is not of organic nature Endocarditis myocarditis and pericarditis are very rare Thrombophlebitis is a complication in about 5 per cent of the patients it develops usually on the legs with an insidious onset Thrombophlebitis rarely occurs before the third week of the illness

Less than 50 per cent of the patients have diarrhea Pea soup stools are present in about 30 per cent of the cases Only about 10 per cent of the patients have diarrhea in the beginning of the disease and severe diarrhea does not develop in more than 20 per cent of the cases Constipation follows the diarrhea and may be very obstinate

Foul breath and sordes are frequent Herpes labialis is only exceptionally seen Nausea and vomiting occur in about 40 per cent of the patients

The abdomen is usually distended and tender upon pressure An enlarged liver may be felt in about 25 per cent of the cases usually after the temperature assumes the continual character The spleen is increased in size it becomes palpable at the end of the first week in about 75 per cent of the patients in other instances later It is not excessively enlarged The organ is tender and soft Spleen enlargement may persist during the entire course of the disease or for only a few weeks or days

Cholecystitis and jaundice occur in about 5 per cent of the cases

Other organ involvements such as cystitis pyelitis neuritis conjunctivitis arthritis osteomyelitis and otitis are not too frequent

(1943) and Felsenfeld (1945) To these basic forms must be added the "classical enteric fever" of Manson Bahr (1945) as well as the pseudosurgical syndrome emphasized by Seligmann et al (1944, 1946) The great importance of the different course of salmonellosis in children is pointed out by Hormaeche et al (1940 1943) As has been emphasized Salmonella infections tend to produce a graver disease in young children The classical typhoid fever, however, often has a light course in this age group due to the greater tendency to resorption of the intestinal infiltrations and lesser tendency to vascular occlusions of the relatively wide intestinal capillaries in children

The clinical forms of salmonellosis will be discussed according to the already enumerated types of this disease

Classical Enteric Fever

This disease is decreasing in the United States (1946) The number of observed cases decreased during the past years to one fifth of its former height The classical picture as described by Manson Bahr (1945) is not too often observed today because of the use of vaccination sulfonamide medication and antibiotics The latter drugs are often applied during the beginning of the disease when it is mistaken for a pulmonary illness dysentery meningitis or sepsis

The incubation period is 3 to 21 days seldom shorter or longer

The course of the classical typhoid type follows the well known pattern characterized by increase of the body temperature during the first week continuous fever during the second and third weeks followed by lysis during the fourth and fifth weeks This fever curve however may be shorter or longer in any of its parts Much material regarding the typical typhoid fever has been collected and published by Manson Bahr (1945) Ganguli and Zeug (1945) and Stuart and Pullen (1946)

According to these descriptions and personal observations the classical typhoid fever begins with a gradually rising temperature or in about 10 per cent of the cases it begins suddenly A sudden onset may be accompanied by chills or rigor These initial chills must be distinguished from the transient chills which occur in many typhoid patients during the later course of the disease In most instances the initial elevations of temperature are not observed by the physician because patients only rarely are seen during the first days of the disease

The temperature reaches 102° to 105° F during the peak of the febrile stage While during the first week (ascending phase) the daily variations of the temperature do not exceed 1° to 1.5° F in the second and third weeks (continuous fever) the difference between maximum and minimum temperatures may be between 1° and 5° F Remitting temperatures begin usually during the third week but often occur as early as the second week The lysis extends for 1 to 2 weeks with marked remissions Thus the entire febrile period lasts 4 to 6 weeks While the classical temperature curve is preserved the fever may last from 3 to 15 weeks

Pharyngitis and bronchitis are more common in typhoid infections than in salmonellosis caused by other organisms

On the whole the clinical picture of typhoid like fever is not characteristic The diagnosis cannot be *made solely by physical examination and* observation

Septicemia

The prodromal stadium may begin with diarrhea which usually disappears during the later course of the disease In such cases the stools are light colored or green and contain mucus

The septicemia proper frequently begins with chills followed by the stage of diarrhea *either immediately or several days later In many instances no* bowel disturbances are present at all and the only symptom is fever In a small number of cases the beginning is insidious with slowly rising temperatures

The fever is remittent There are great differences between the morning *and the evening thermometer readings 5° F or more Continuous fever may* be present for some days but its general character remains remittent The duration of the febrile episode is irregular 3 to 6 weeks may be considered average

There is malaise headache pain in the back and in the limbs anorexia and *thirst Delirium may be present Insomnia and apathy are frequent* The tongue is heavily coated and the mouth is dry

The pulse is soft and usually accelerated A dicrotic pulse is not often observed

Abdominal distention and pain may be present but often there is no intestinal *discomfort The spleen is usually enlarged soft and tender*

Rose spots are very rarely seen

Bronchitis is often the most outstanding symptom and may dominate the clinical picture to such an extent that only the diagnosis of bronchitis or bronchopneumonia is made

Salmonella septicemia is often observed in newborn babies and in older persons in the latter case usually superimposed upon a wasting sickness as *arteriosclerosis diabetes* tuberculosis leucemia nephritis or malaria The presence of these diseases may stand so strongly in the foreground that the possibility of a superimposed salmonellosis is not considered especially in the absence of diarrhea

Salmonella septicemia frequently leads to localized affections In children meningitis is the most frequent and most feared localization Salmonella meningitis in children was extensively studied by Neter (1944) who called attention to the necessity of considering Salmonellae as a possible cause in every case of meningitis *The clinical picture of Salmonella meningitis does* not show symptoms which permit its differentiation from acute meningitis caused by other nonacid fast organisms

Cholangitis cholecystitis pleuritis pericarditis thrombophlebitis osteomyelitis and pelvic inflammations often occur during or after Salmonella

Rose spots (roseola typhosa) occur during the second week, less frequently during the first or third week in about 30 per cent of the patients These spots are pale slightly raised macular, round oval or slightly irregular, about 2 to 5 mm in diameter varying considerably in shape and size and disappearing upon pressure There may be few or many roseolae distributed on the abdomen chest and extremities most often on the trunk The face is rarely involved The soles the palms and the scalp do not become involved The spots do not itch Roseola appears in crops lasting for 2 to 6 days

Among the other skin affections occurring in typhoid fever furuncles decubiti and other ulcerations are the sign of uncleanliness insufficient nursing care and circulatory weakness

Relapses of typhoid fever are not rare they are observed in about 15 per cent of the cases They develop 3 to 40 days after the termination of the typical fever curve and last for 1 to 6 weeks They are more frequent in patients treated with antibiotics

Typhoid Like Fever (Salmonella Fever)

In the tropics Salmonella fever is frequently caused by Salmonellae other than the typhoid bacillus In persons who have been immunized against typhoid fever the classical picture of typhoid is rarely observed The disease very often takes the course of Salmonella fever While children suffer more often from grave forms of salmonellosis a mild course of typhoid is not rare in them The fever however usually reaches a far higher peak than in adults

Salmonella fever differs from the classical typhoid fever by generally having a shorter duration Cases with a prolonged course however have also been observed The fever rarely exceeds 104° F

The disease may begin suddenly with a chill though an insidious onset is far more common Anorexia headache and malaise are frequent symptoms The tongue is usually coated The patient does not have the characteristic toxic appearance of a person suffering from classical typhoid fever

Epistaxis may occur Labial herpes has also been described

There is no discrepancy between the temperature and the pulse rate in most cases

Abdominal pain is usually intense There is distention and often meteorism The spleen may or may not be enlarged The meteorism particularly in children does not always permit palpation of this organ

Rose spots are frequently observed in the tropics in paratyphoid B fever but are usually absent in other Salmonella infections

Diarrhea may be entirely absent Constipation throughout the entire course of the disease is often experienced in children On the other hand profuse diarrhea beginning during the first or second week of the disease is not uncommon

A pseudosurgical syndrome assuming the picture of an appendicitis cholecystitis or pelvic inflammation is often present.

ent state will reveal vague symptoms which may be attributed to the gall bladder or to the kidneys Many carriers are accustomed to abdominal discomfort and do not complain about them

COMPLICATIONS AND SEQUELAE

Any clinical form of salmonellosis may give rise to complications or sequelae

Perforations

Perforations are the most feared complications in typhoid fever Perforations occur during the period of intestinal ulcerations in about 2 to 5 per cent of the typhoid cases

The beginning is usually sudden Tenderness and rigidity of the abdomen develop within a very short time Hiccup is frequently present Collapse occurs very often During the later course symptoms of peritonitis develop

Hemorrhages

It is often difficult to draw the line between "normal" bleeding from typhoid ulcers and hemorrhage An alarming hemorrhage consists of the expulsion of tarry *stools* or even pure blood without a considerable admixture *of fecal material Hemorrhages* from the higher parts of the small intestine may cause hematemesis Such intensive bleeding is observed *as often as in about 10 per cent of the patients in the tropics There may be only one large* hemorrhage or the bleeding may be repeated The amount of blood varies considerably in each case

Respiratory Disorders

Bronchitis is not uncommon in salmonellosis Pneumonia or bronchopneumonia develops in about 10 per cent of the cases of typhoid fever and Salmonella septicemia Salmonellae may be present in the sputum or the lung involvement may be caused by secondary invaders

Manson Bahr (1945) calls attention to the possible activation of tuberculosis during salmonellosis and suggests that pulmonary tuberculosis be *considered in every case of prolonged* bronchitis or bronchopneumonia during typhoid fever The author noted that in cases of pulmonary tuberculosis the *clinical condition* became worse due to *Salmonella paratyphi B* infections in a children s hospital

Pleuritis occurs in about 3 per cent of the cases Empyema is rare

Circulatory Disturbances

Thrombophlebitis is observed in typhoid fever and in *Salmonella septicemia It* is usually a late complication and the beginning is insidious The legs are *most frequently involved* Thrombophlebitis may cause embolism with all its sequelae

Endocarditis myocarditis and pericarditis are rather rare They are observed in less than 1 per cent of Salmonella infections The myocardial involvement is often demonstrated only with the aid of electrocardiography

septicemia An abscess may develop in nearly any part of the human body following such an infection

There is very little in the clinical picture of Salmonella septicemia that would permit the diagnosis of this disease solely on the ground of physical examination and observation

Enteritis

The incubation time of Salmonella enteritis varies from 8 hours to 2 weeks

The fever has nothing in common with the curve observed in typhoid In most cases there is no fever at all About 40 per cent of the patients have low grade fever lasting from 2 to 4 days The temperature seldom exceeds 102° F Exceptionally chills high fever and prostration with quickly fatal ending are observed usually in otherwise sick debilitated persons

The onset is sudden in 90 per cent of the cases There is diarrhea similar to bacillary dysentery The number of stools varies from 2 to 20 a day The stools contain much mucus but usually no blood

There is abdominal distention pain and meteorism The pain may be localized in the appendiceal gall bladder pelvic or rectosigmoidal region It must be kept in mind that true Salmonella appendicitis cholecystitis and salpingitis do exist and therefore these symptoms must be evaluated carefully Dicrotic pulse or an acutely enlarged spleen is very rarely seen

There is usually little toxicity Headache and malaise may be present Rose spots are not observed Bronchitis is rare Vomiting is a frequent symptom chiefly in the beginning of the disease

The proctoscopic examination reveals in about 30 per cent of the cases an inflamed intestine similar to that observed in mild bacillary dysentery

Syndromic Salmonellosis

As previously stated salmonellosis may occur under the picture of appendicitis cholecystitis or pelvic inflammation Such symptoms may be due to acute pathology of the intestines in the neighborhood of the appendix gall bladder or pelvic organs On the other hand Salmonellae may attack these organs The differential diagnosis is made by clinical examination and laboratory investigation

In the tropics salmonellosis often occurs in a malarial or relapsing fever type when the fever falls for a few days and rises again after such intervals According to the length of the periods between the attacks a malarial or a relapsing fever like curve may be observed

The dengue like or influenza like type of typhoid is characterized by high fever of short duration involvement of the respiratory organs and critical fall of temperature

Carrier State

As a general rule no symptoms are observed in chronic carriers In several instances however thorough examination of the history and of the pres

It must be pointed out that the skin of persons living in the rural tropics often suffers from bacterial and mycotic lesions as well as *from bites of arthropods* Rose spots must therefore be evaluated carefully Furunculosis is not rare in hot regions during febrile salmonellosis

Intestinal Tract

As a rule lesions in the intestinal tract heal without scar formation In some cases however chronic nonspecific colitis has been observed as a sequela of Salmonella enterocolitis Salmonellae have also been recovered from spastic colitis (irritable colon) mucous colitis and regional ileitis While an irritable colon or ulcerative colitis is less frequently observed after salmonellosis than in connection with a Shigella *Endamoeba histolytica* or streptococcal infection *the role of Salmonellae in regional ileitis is a matter which* merits further attention We have isolated Salmonellae from 2 (out of 6) cases of regional ileitis the organisms were identified as *S typhimurium* and *S montevideo* respectively

LABORATORY DIAGNOSIS

Isolation of Salmonellae

The methods recommended for the isolation of Salmonellae from feces and urine are described in Chapter 71

One must keep in mind that several repeated stool examinations are necessary to recover the causative agent Both stools and urine must be investigated

In the classical typhoid fever in Salmonella fever and septicemia the organisms are cultured from the blood stream and from the bone marrow with relative ease Methods recommended for such cultures are described in Gradwohl *Clinical Laboratory Methods and Diagnosis* ed 4 1948 pp 156a 157b In this chapter we wish only to point out that best results are obtained when every blood sample is inoculated simultaneously into three media brain heart infusion with p amino benzoic acid agar and penicillinase fluid thioglycollate medium and trypticase soy broth Salmonellae grow in the first and last of these liquids *If gram negative rods are seen in smears* from these culture fluids blood and tryptose agar plates are streaked from *them* Salmonella colonies which grow well under aerobic and anaerobic conditions and in a carbon dioxide atmosphere are identified by the usual procedure

It must be kept in mind that blood and bone marrow cultures are positive for Salmonellae more often during the first period of the disease than during the later weeks

Agglutination Reactions

The most frequent types of agglutination tests performed in salmonellosis are

The Tube Agglutination Test (Widal Reaction) —This test is carried out by preparing serial dilutions of the patient s serum from 1 10 to 1 2560 and adding suspensions of Salmonellae to each *dilution*

Decubiti develop in patients with circulatory disturbances and in persons lacking proper nursing care

Cholangitis and Cholecystitis

These are more frequent complications and sequelae of salmonellosis than is generally known About 5 per cent of all Salmonella infections show a low grade cholecystitis and more than 25 per cent reveal an impaired liver function when tested with sensitivity reactions e g the cephalin cholesterol flocculation test

Pathologic changes in the gall bladder are often found in so called healthy chronic carriers of Salmonellae

Nervous System Disturbances

Meningitis is frequent in small children Neuritis is infrequent but has been described as a sequela in typhoid and paratyphoid infections

Meningismus is not rare It can be differentiated from meningitis by laboratory examination

Genitourinary Lesions

Salpingitis, parametritis or perimetritis has been observed in about 1 per cent of female patients suffering from salmonellosis Salmonella endometritis seems to be rare The symptoms do not differ from those caused by other pyogenic organisms

Pyelitis and pyelonephritis belong among the less common Salmonella infections Involvement of the urinary system caused by secondary invaders is not rare in typhoid fever typhoid like fever and Salmonella septicemia While the organisms are excreted through the urine in about 25 per cent of febrile salmonellosis lesions of the kidneys or the urinary bladder due to Salmonellae themselves are infrequent

Pregnant women often miscarry during febrile salmonellosis Enteritis however is easily tolerated during gestation

Locomotor Apparatus

Salmonella arthritis belongs among the rarities Osteomyelitis chiefly in children is more frequently observed Typhoid bacilli *S typhimurium* and *S paratyphi B* are the chief offenders The ribs the spine and the bones of the extremities are the most frequent seats of suppurative lesions which show very little tendency to spontaneous healing

Abscess Formation and Skin Lesions

Salmonellae chiefly those which cause septicemia may cause localized suppurative lesions in the form of abscesses of the skin of the brain or of the internal secretory glands Pus in the pleural and abdominal cavities may contain Salmonellae

Atrophic skin lesions may occur and alopecia often develops after typhoid fever

Hematology

Anemia is not rare in salmonellosis Cases with fever show most commonly a decrease in the number of red blood cells and of hemoglobin The lowest findings are frequently recorded during the third or fourth week of the disease

A slight increase in the number of white blood cells is not unusual in the earliest days of salmonellosis 8 000 to 11 000 leucocytes per cubic millimeter are frequently counted during this period

Leucopenia is the rule during the later course of febrile salmonellosis There is a decrease in the polymorphonuclear cells with a relative increase in the mononuclears The number of white blood cells returns to normal by the end of the sickness

The leucopenia is caused by the leucotoxin the presence of which has been proved in a number of Salmonella cultures

Perforations of the intestine suppurative processes secondary infections and other similar conditions may cause leucocytosis

Urinalysis

Urinalysis frequently reveals the presence of protein during the first part of febrile salmonellosis Casts are observed in a small percentage of the cases

The diazo reaction is frequently positive in febrile salmonellosis Reports are lacking on large scale examinations in cases suffering only from Salmonella enteritis

PROGNOSIS

The over all mortality of salmonellosis is 5 to 6 per cent The fatality rate differs according to the age group and the clinical form of salmonellosis In America the death rate of classical typhoid fever varies between 10 and 15 per cent in children from 5 to 10 per cent in old people from 25 to 35 per cent The mortality of Salmonella fever is 5 to 10 per cent in children 10 to 15 per cent in old people 15 to 20 per cent The fatality of Salmonella septicemia is 15 to 20 per cent in children 40 to 60 per cent in old people 30 to 70 per cent Enteritis kills 1 to 3 per cent of the patients *

DIFFERENTIAL DIAGNOSIS

Sepsis may be differentiated by the result of blood cultures It is essential that no sulfonamides and no antibiotics be given to the patient before the blood is drawn

Miliary tuberculosis is often difficult to differentiate from febrile salmonellosis Frequent cultures of blood stools and urine for Salmonellae ophthalmoscopic examination x ray pictures of the chest and in many cases the rose spots will determine the diagnosis

*Recent antibiotics have greatly reduced these mortality rates.

The Slide Agglutination Test (Spot Agglutination Test) —This reaction was devised by Welch and Stuart (1936) Small decreasing amounts of the patient's serum are placed with a Kahn pipette into excavations of a glass plate Three hundredths amounts of a heavy suspension of Salmonellae are added to each drop of serum and the results are read after a few minutes

The Whole Blood Test —The whole blood test was described by Prumpt (1940) A drop of freshly collected or dry blood is mixed with 1 drop of antigen which contains sodium citrate Agglutination developing within 1 minute is considered significant and equivalent to a positive Widal test with at least a 1 80 dilution of the serum

The Vi Agglutination Test —The technic and significance of the Vi agglutination test have been discussed by Prower (1944) Soman (1945) and Gunther (1946) (Gradwohl *Clinical Laboratory Methods and Diagnosis* ed 4 1948 p 1468) This test is helpful in detecting typhoid carriers On the other hand it is positive in a fairly large number of uninfected persons

After vaccination or previous attacks of salmonellosis and in diseases caused by agents other than Salmonella (malaria pyelitis etc) sera often give positive agglutination tests On the other hand Salmonella infections which involve only the intestinal tract and even Salmonella fever due to certain strains (as *S paratyphi A*) do not show an increased agglutination titer

Frequently gross incongruities have been observed between the strain isolated from the patient and the result of the agglutination tests The antigens commonly used for the serologic detection of salmonellosis in America are prepared from the typhoid bacillus and from *S paratyphi A* and *S paratyphi B* while the great majority of salmonelloses are caused by other organisms (Bornstein 1943 Seligmann et al 1946 Felsenfeld 1945) When the usual antigens are tested an amazing maze of negative and positive findings results There are many cross reactions between Salmonellae It is recommended therefore that polyvalent antigens be used Bornstein (1943) and Felsenfeld (1947) devised such agglutinogens A positive reaction with these antigens indicates only that the patient has Salmonella antibodies

The difficulties described above warrant a cautious evaluation of agglutination tests in salmonellosis It must be kept in mind that negative results are not only possible but frequent and that positive agglutination tests may be due to other causes The following procedure is therefore recommended

The agglutination test should be employed first in the beginning of the disease It must be repeated 1 week to 10 days later Significance must be attributed only to high titer (1 80 or more) reactions both with O and H antigens and to agglutination tests which upon repetition show at least a four fold increase of one or both of the agglutination titers

Recently developed excellent culture methods for the detection of Salmonellae from the patient reduce the importance of serologic tests

Sulfonamide Drugs

Kolmer and Rule (1941) and Lawrence and Sprague (1941) found sulfonamides slightly effective in vitro and in animal experiments with Salmonellae. Hardy (1943) was able to reduce temporarily the number of excreted typhoid bacilli by sulfonamide medication. Hutner and Zahl (1942), Rachmilewitz and Braun (1943), and others found that sulfonamide drugs reduced the toxicity of Salmonellae. Most authors, however, are very skeptical about the use of sulfonamide preparations in salmonellosis.

We have seen but little influence of sulfonamides upon salmonellosis except in the reduction of toxic symptoms. The fever curve may be altered and the organisms are more difficult to isolate from the patient during sulfonamide treatment. The use of such drugs, therefore, is recommended only in septic cases and in carriers after gall bladder removal (Manson-Bahr, 1943).*

Antibiotics

Thomas and Levine (1945) and Riser et al. (1946) studied the action of penicillin upon Salmonellae. Penicillin caused the appearance of involution forms of typhoid bacilli. Different strains showed varying susceptibility to penicillin. About 10 units per c.c. were necessary to prevent the multiplication of typhoid bacilli.

According to our experiments, the susceptibility of Salmonellae to antibiotics shows great variations. In most cases of salmonellosis the only result of penicillin and streptomycin medication is that it impairs the effectiveness of *laboratory diagnostic methods.*

Bigger (1946), McSweeney (1946) and Comerford et al. (1946) found that penicillin and sulfathiazole given simultaneously act synergetically upon cases and carriers of typhoid fever. This method of treatment deserves further trial. In vitro experiments show that combinations of soluble sulfonamide drugs and antibiotics (penicillin and streptomycin) have a very favorable action upon Salmonellae. Shwartzman (1945) was able to improve the action of penicillin by *adding to it methionine, threonine and methionine sulfoxide.*

Streptomycin has been regarded as a most promising antibiotic. It was first tested in vitro and in animals by Schatz et al. (1944), Jones et al. (1944) and West et al. (1945). Extensive experiments in human salmonellosis were carried out by Elias and Durso (1945) and Reimann et al. (1945).

The dose of streptomycin is 1 to 4 million units per day, given per os or injected. In our experience 4 million units daily are necessary *for the* average case. It is important to keep in mind that the susceptibility of Salmonella strains to this antibiotic varies greatly. Unwanted reactions from the liver, skin, and other organs are frequent. The treatment must be carried out for a long time, at least 4 days after the symptoms have disappeared. Because of its collateral action, streptomycin should be reserved for serious cases of salmonellosis and supported by sulfonamides. Daily doses of 2 to 4 Gm. of

*See also Chapters 64 and 65.

Typhus shows a rapid pulse se in the white blood cells, and a typical eruption

Malaria and relapsing fever l by the examination of blood smears The consistency and s in malaria are different in many instances

Beginning meningitis may l l t typhoid fever and vice versa The type of vomiting the rigidity k which develops during the third to fifth day, and Kernig s symp t l t the proper diagnosis It must be kept in mind however that S ll n lla meningitis is not as rare as generally thought Many cases of S ll ell meningitis are diagnosed as "influenza meningitis' when the diff tiation is based solely upon the finding of ' gram negative pleomorphic r ls resembling influenza bacilli" in the smears from the spinal fluid Such rganisms are often proved in culture as Salmonellae

Brucellosis has its own immunology and bacteriology The brucellergin test the opsonocytophagic index and in many cases, the specific agglutination and blood culture will help to establish the diagnosis of an attack of brucellosis resembling Salmonella fever

Appendicitis differs from Salmonella pseudoappendicitis by the increase in white blood cells It must be remembered however that an initial slight leucocytosis is not rare in salmonellosis The true appendicitis caused by Salmonella cannot be differentiated from appendicitis evoked by other factors

Tuberculous peritonitis in children may cause numerous differential diagnostic difficulties Laboratory examination gives proper leads for the diagnosis

Gastroenteritis caused by Staphylococci differs from Salmonella infections by the shorter period of incubation lack of fever preponderance of vomiting abdominal cramps diarrhea and prostration

Streptococcus gastroenteritis is usually mild with nausea abdominal pain and diarrhea

The last two diseases as well as atypical cases of cholera and bacillary dysentery can be differentiated only by the isolation of a Salmonella Shigella or Vibrio from the patient or of the cocci from the incriminated food

TREATMENT

Specific Serum

Serotherapy is recommended in classical typhoid fever Felix produced a serum which proved promising in animal experiments and in clinical trials Felix s serum is given in 25 c c doses on 3 successive days during the early course of the disease The serum reduces the toxic symptoms Serotherapy during the later course of Salmonellosis is valueless

Sera against other Salmonellae are not available Their use would be restricted to septic cases

The diet must be supplemented with vitamins preferably in injections Fifty to 100 mg thiamine hydrochloride 500 to 1 000 mg ascorbic acid and 1 to 2 mg vitamin K must be injected daily If infusions or transfusions are given these substances are dissolved in the fluid Folic acid may be added

Specific Chemotherapy

Reiter and Marburg (1943) recommended the use of tin stearate and colloidal metallic tin Twenty 0 012 Gm tablets are given the first day 10 tablets per day during the subsequent 9 days

Kleeberg (1941 1945) advocates the use of mandelic acid in typhoid Severe diabetes peptic ulcer and nephritis are contraindications for this treatment *Good results have been observed in mild cases*

Clark et al (1945) observed excellent results with gentian violet in animals infected with Salmonellae This method may also find use in human medicine

Constipation and Diarrhea

Cathartics must never be given in constipation A tepid saline enema will bring prompt action without endangering the patient

Diarrhea was considered a symptom worthy of suppression by many authorities of the European Continent Large amounts of kaolin and animal charcoal were given About the latter Thomayer (1919) reporting on a long series of typhoid cases remarked It colors the stools black I have not observed any other effect of this medication

It is customary to give absorbents in Salmonella enteritis Kaolin alone or in combination with magnesium is the drug of choice

Against abdominal discomfort during Salmonella enteritis combinations of papaverine and belladonna occasionally with a small addition of a barbiturate may be used In most cases however one does not find it necessary to employ such medication

Complications

Oral hygiene is of utmost importance A cold cream can be used to treat the lips

Bronchitis bronchopneumonia and pneumonia are treated according to the rules of the management of such diseases Ipecac (ipecacuanha) however is often badly tolerated and codeine may increase the constipation

When an intestinal perforation occurs an operation must be contemplated Whole blood 250 to 500 c c or 500 to 1 000 c c of plasma are given daily Glucose infusions are also indicated Generous doses of streptomycin and penicillin should be given together with sulfaguanidine sulfasuxidine or sulfaphthalidine

In cases of hemorrhage morphine or Pantopon is injected Most authorities recommend refraining from the use of opium Large transfusions

sulfapyridine sulfathiazole sulfadiazine or phthalyl sulfacetimide given with an equal amount of sodium bicarbonate are recommended for this purpose Sulfonamide medication is possible however only when the urinary output can be maintained at a high level

As this book goes to press two new antibiotics aureomycin and Chloromycetin have been introduced in the treatment of salmonellosis Experiments have shown that these drugs are more effective in salmonellosis than is streptomycin Dihydrostreptomycin a detoxicated form of streptomycin has also been introduced *

Vaccine Therapy

Vaccine therapy favored so much in the past has few adherents at present Magrou and Brison (1945) recommended it using alcoholized vaccines

Transfusions

As Dewar (1946) pointed out convalescent whole blood has a beneficial action upon typhoid fever Even when convalescent blood is not available whole blood in doses of 500 c c is strongly indicated in hemorrhages

Plasma has proved very beneficial in toxic cases About 250 to 500 c c should be given daily

In dehydration when blood products are not available infusions with 5 per cent glucose are recommended 2 to 4 liters are given daily Plasma injections may be combined with glucose infusions

Hydrotherapy

When the temperature is higher than 102° F washing with water at 20° to 25° C 3 or 4 times a day with a sponge is recommended Some aromatic spirits or vinegar may be added to the water

An ice bag may be applied to the head when the patient s condition indicates it

Dietary Treatment

The ancient starvation diet is no longer used in typhoid fever A diet consisting of 4 000 to 5 000 calories is given The protein intake must not fall below 75 Gm Manson Bahr (1945) calls attention to the necessity of selecting for the patient such food from the dietary list that he likes

The fluid intake must be 4 to 6 liters a day Fruit juices weak tea or coffee and soups will make up most of this amount To increase the calorie value lactose or sucrose should be added to the fluids

Meat broth and cream soups are recommended Milk is best tolerated in the form of custards chocolate and malted milk Four to 8 eggs are recommended each day Butter is given frequently

Toast crackers mashed potatoes well cooked rice tapioca strained cereals farina Jello puddings and oranges complete the diet

No food is given during intestinal bleeding

* At the time of proofreading neomycin and polymyxin D as well as [illegible] have also proved beneficial in salmonellosis

4 Sanitary Water Supply

Wherever wholesome and safe water has been secured *typhoid fever has* decreased or even disappeared If well protected natural sources are not available filtration chlorination or the simple but very effective method of *boiling will produce good water*

5 Proper Sewage Disposal

Protection of the community from fecal infection can be accomplished only by instituting proper rules for the disposal of fecal and urinary material Education of the population is the first step to be taken to accomplish this measure Septic tanks and properly operating sewage systems are the most effective measures against intestinal infections Where not even septic tanks can be installed the borehole latrine should be tried

6 Other Sanitary Measures

Shellfish have *often been proved to convey salmonellosis Control of* shellfish is therefore essential

Flies may transfer Salmonellae passively from feces to food Control of flies is necessary for any successful antienteric program

Fomites such as books used by salmonellosis patients easily transfer the infection Disinfection is essential

7 Protective Immunization

The most commonly used vaccine consists of 1 000 million typhoid bacilli and 750 millions each of *S paratyphi A* and *B* per c c At weekly or 10 day intervals 0 5 1 0 and 1 0 c c is injected under the skin If revaccination is necessary 0 1 c c of the vaccine is injected under the skin This vaccine is the T A B vaccine The past war years brought much progress in its composition and application The typhoid organism used in the T A B vaccine was *the Rawlings strain* which was substituted by the Foxill #58 strain isolated from a carrier in Panama

Much attention is being paid to the importance of the Vi antigen in typhoid vaccination Such a vaccine was devised by Felix *It contains in each* c c 1 000 million typhoid Vi and 500 millions of each *S paratyphi A B* and *C* organisms Two tenths to 0 25 c c is injected first After 3 weeks 0 4 to 0 5 c c is given

Luippold and Longfellow (1942 1943 1946) proved in a long series of experiments that there is some cross protection between typhoid and paratyphoid B organisms while *S paratyphi A* does not show cross protection with any of these Salmonellae They found too that the T A B vaccine protects against the organisms from which it is prepared against *S enteritidis* and against *S typhimurium* but not against *S choleraesuis* and *S oranienburg* It has also been proved that the Vi antigen from *S ballerup* or *E coli* 5396 protects against

500 to 1,000 c c of whole blood, are indicated No food is given per os for few days when weak tea and milk with lactose or sucrose may be tried Manson Bahr (1945) recommends 2 to 4 mg vitamin K daily, and twice a da an enema with 1 liter of tepid saline During the later course of the diseas the amount of food is slowly increased until the full Salmonella diet is given

Other complications are treated according to the rules of medical or sur gical therapy applied to pyogenic infections

Carriers

Carriers may often be cured by gall bladder extirpation In some states e g Massachusetts this procedure is officially recommended Sulfonamid treatment is indicated after the operation

PROPHYLAXIS

The general rules for prevention of salmonellosis can be summarized as

1 Search for Human Carriers

Every person who has had salmonellosis should be subjected to repeated stool and urine examinations After febrile salmonellosis the bile should also be examined for Salmonellae

2 Eradication of Animal Disease

Fowl hogs and cows are known carriers of salmonellosis Flocks o birds should be protected against Salmonella infections by enforcing quaran tine rules and vaccination Carriers are frequent among animals the meat o which is used for human consumption Such animals do not necessarily show gross pathologic changes except by thorough inspection Extensive bac teriologic surveys are therefore needed to clear these foci of infection

3 Protection of Food

Protection From Human Carriers—Only persons known not to harbor Salmonellae Shigellae or *Endamoeba histolytica* should be permitted to handle food Food handlers should be subjected to periodic examinations

Destruction of Salmonellae in Infected Foods—Meat and milk of infected animals and meat and eggs of infected birds often contain Salmonellae Pas teurization of the milk is a satisfactory measure for destroying Salmonellae Unfortunately eggs and meat are not often brought to a sufficiently high tem perature during cooking to destroy Salmonellae in the inside portions of the meat puddings and other products

Proper Storage of Food—Rodents are often infected with Salmonellae and may contaminate food during storage if they have access to it

Proper Cleaning of Vegetables Eaten Raw—Vegetables fertilized with human or animal excreta or contaminated by fowl fecal material may carry Salmonellae Proper washing and cooking will destroy these organisms

4 Sanitary Water Supply

Wherever wholesome and safe water has been secured typhoid fever has decreased or even disappeared If well protected natural sources are not available filtration chlorination or the simple but very effective method of boiling will produce good water

5 Proper Sewage Disposal

Protection of the community from fecal infection can be accomplished only by instituting proper rules for the disposal of fecal and urinary material Education of the population is the first step to be taken to accomplish this measure Septic tanks and properly operating sewage systems are the most effective measures against intestinal infections Where not even septic tanks can be installed *the borehole latrine should be tried*

6 Other Sanitary Measures

Shellfish have often been proved to convey salmonellosis Control of shellfish is therefore essential

Flies may transfer Salmonellae passively from feces to food Control of flies is necessary for any successful antienteric program

Fomites such as books used by salmonellosis patients *easily transfer the* infection Disinfection is essential

7 Protective Immunization

The most commonly used vaccine consists of 1 000 million typhoid bacilli and 750 millions each of *S paratyphi A* and *B* per c c At weekly or 10 day intervals 0 5 1 0 and 1 0 c c is injected under the skin If revaccination is *necessary 0 1 c c of the vaccine is injected under the skin* This vaccine is the T A B vaccine The past war years brought much progress in its composition and application The typhoid organism used in the T A B vaccine was the Rawlings strain which was substituted by the "Povill #58" strain isolated from a carrier in Panama

Much attention is being paid to the importance of the Vi antigen in typhoid vaccination *Such a vaccine was devised by Felix It contains in each c c 1 000 million typhoid Vi and 500 millions of each S paratyphi A B* and *C* organisms Two tenths to 0 25 c c is injected first After 3 weeks 0 4 to 0 5 c c is given

Luippold and Longfellow (1942 1943 1946) proved in a long series of experiments that there is some cross protection between typhoid and paratyphoid B organisms while *S paratyphi A* does not show cross protection with any of these Salmonellae They found too that the T A B vaccine protects against the organisms from which it is prepared against *S enteritidis* and against *S typhimurium* but not against *S choleraesuis* and *S oranienburg* It has also been proved that the Vi antigen from *S ballerup* or *E coli* 5396 protects against

the Vi factor of the typhoid bacillus Luippold (1946) prepared a stable extract of the Vi antigen from *E coli* 5396/38 which is used as an additional immunizing agent but not mixed into the T A B vaccine because of the clinical reactions caused by such mixtures

Freund and Bonanto (1946) found that killed organisms injected in a lanolin oil water mixture give rise to antibodies which persist for a very long time Chime (1942) Morgan et al (1943 1945) and Linton and Jennings (1943) greatly contributed to the development of chemically purified vaccines

According to Manson Bahr (1945) the Royal Air Force of Great Britain during the war used a T A B vaccine with sodium lauryl sulfate

Alum precipitated typhoid paratyphoid vaccines were described by Leon et al (1941) and Shevchenko (1942) These vaccines are given in a single injection

Ultraviolet irradiation was used successfully for the preparation of typhoid paratyphoid vaccines by Troitskii et al (1942) and by Oliver and Bonet Maury (1946) Remlinger described a chromo vaccine (1945), Ruiz Merino (1946) a brilliant green vaccine

Oral vaccination is not used in the Americas Perhaps the last proof of the uselessness of such vaccines was supplied by Moor and Wallace (1941)

Much interest is paid to intracutaneous T A B vaccination This method was found very effective by Leme and Carrijo (1943) and Carrijo et al (1945) The intervals and dosage vary according to the authors

Kamp (1943) gave children weekly injections of 0 1 0 15 and 0 2 c c No generalized reactions were observed

Ristori and Schwartz (1944) injected at 3 week intervals 0 05 0 1 and 0 15 c c The results were good

Reyes (1945) used 3 injections 0 1 c c each at monthly intervals No undesired reactions were observed and the results were better than those achieved by using the classical injection route

Luippold (1946) developed a mouse protection test for the evaluation of Salmonella vaccines This test together with the determination of the amount of mouse protective antibodies in the serum of the vaccinated individuals is the best measure for the control of the immunization

The many million doses of T A B vaccine given during the war proved its prophylactic value and innocuousness Tilden and Arnold (1943) however described histiocytic reactions after intradermal injections which persisted for many months de Monte and Gupta (1941) brought up the question of the so called provocative typhoid which is observed when exposed persons are immunized It is believed that if the Vi antigen is used a negative phase of a few days duration does not develop after the injection of the vaccine and consequently the vaccinated person does not become more susceptible to typhoid fever during the negative phase

It is recommended that every year revaccination be carried out with a single dose of the vaccine

SHIGELLOSIS

(Bacillary Dysentery)

DEFINITION

The terms "shigellosis" and "bacillary dysentery" are frequently used to designate the *same disease* *Shigellosis, however, is the correct name of infections caused by Shigellae* Bacillary dysentery is a clinical syndrome consisting of frequent bowel movements with the evacuation of mucus and, in many cases, blood or pus Bacillary dysentery is most frequently due to Shigellae Neter (1942) and others proved that bacteria other than Shigellae *may also cause bacillary dysentery, chiefly in children and old persons* Paracolon organisms, Protei, and Pseudomonades are often the agents of such disturbances While discussion is still progressing on the pathogenic power of certain paracolon and Proteus strains, most Shigellae found in man are considered pathogenic

ETIOLOGY

Shigellae are gram negative, nonspore forming, noncapsulated, nonmotile organisms which form acid but not gas from dextrose and, frequently, also from other carbohydrates They grow well on the usual media under aerobic and anaerobic conditions They do not produce acetylmethylcarbinol

The present American classification of Shigellae is based upon the studies of Neter (1942) According to Neter, Shigellae may be divided into four groups

I Mannitol negative, lactose negative—*Sh dysenteriae* Shiga and Sachs, *Sh ambigua* Schmitz, and *Sh newcastle*

II Mannitol positive, lactose negative—*Sh paradysenteriae* and *Sh alkalescens*

III Mannitol negative, lactose positive—no human pathogen

IV Mannitol positive, lactose positive—*Sh sonnei* and *Sh dispar*

Sh dysenteriae Shiga and Sachs are very rare in America. *Sh ambigua* is more frequent, especially in South America

The most frequent strains of *Sh paradysenteriae* are I, II, III, IV, and VI. The geography of these types was recently discussed by Hardy (1945), Hardy et al (1942, 1945), Kuhns (1943), Fulton (1945), and Nelson et al (1946) in North America, Macumber (1942) in Panama, Pot (1945) in Curacao, Hormaeche et al (1943) in South America, Fortune and Ferris (1945) in New Guinea, Nelson et al (1945) in India, Yañez (1944) in Spain, Westermann (1944) in the Netherlands, Elrod and Wormus (1946) in France, Boyd (1946) in the Middle East, and Young (1947) in global relations It seems that Boyd's 88 type is rapidly spreading It was disseminated over Europe by the German Army

Sh alkalescens is not considered pathogenic by most authors

Sh sonnei was first described by Duval in America but it is often called the Sonne Kruse bacillus The designation "*Shigella sonnei*" seems to be firmly entrenched Because of the mild clinical form produced by this organism, the disease is often diagnosed as "food upset," "summer diarrhea," "institutional diarrhea," or "just a simple intestinal indisposition " Many cases are reported from children's institutions, mental hospitals, and military camps *Sh sonnei* infections are observed in all parts of the world

Sh dispar includes *Sh ceylonensis* and *Sh madampensis* The pathogenicity of *Sh dispar* has been questioned by most authors

EPIDEMIOLOGY

The *means of spread* of Shigellae have been discussed by Neter (1943), Manson Bahr (1943), and Kuhns (1943)

the Vi factor of the typhoid bacillus Luippold (1946) prepared a stable extract of the Vi antigen from *E coli* 5396/68 which is used as an additional immunizing agent but not mixed into the T A B vaccine because of the clinical reactions caused by such mixtures

Freund and Bonanto (1946) found that killed organisms injected in a lanolin oil water mixture give rise to antibodies which persist for a very long time Cline (1942) Morgan et al (1943 1945) and Linton and Jennings (1943) greatly contributed to the development of chemically purified vaccines

According to Manson Bahr (1945) the Royal Air Force of Great Britain during the war used a T A B vaccine with sodium lauryl sulfate

Alum precipitated typhoid paratyphoid vaccines were described by Leon et al (1941) and Shevchenko (1942) These vaccines are given in a single injection

Ultraviolet irradiation was used successfully for the preparation of typhoid paratyphoid vaccines by Troitskii et al (1942) and by Oliver and Bonet Maury (1946) Remlinger described a chromo vaccine (1945) Ruiz Merino (1946) a brilliant green vaccine

Oral vaccination is not used in the Americas Perhaps the last proof of the uselessness of such vaccines was supplied by Moor and Wallace (1941)

Much interest is paid to intracutaneous T A B vaccination This method was found very effective by Lime and Carrijo (1943) and Carrijo et al (1945) The intervals and dosage vary according to the authors

Kamp (1943) gave children weekly injections of 0 1 0 15 and 0 2 c c No generalized reactions were observed

Ristori and Schwartz (1944) injected at 3 week intervals 0 05 0 1 and 0 15 c c The results were good

Reyes (1945) used 3 injections 0 1 c c each at monthly intervals No undesired reactions were observed and the results were better than those achieved by using the classical injection route

Luippold (1945) developed a mouse protection test for the evaluation of Salmonella vaccines This test together with the determination of the amount of mouse protective antibodies in the serum of the vaccinated individuals is the best measure for the control of the immunization

The many million doses of T A B vaccine given during the war proved its prophylactic value and innocuousness Tilden and Arnold (1943) however described histiocytic reactions after intradermal injections which persisted for many months deMonte and Gupta (1941) brought up the question of the so called provocative typhoid which is observed when exposed persons are immunized It is believed that if the Vi antigen is used a negative phase of a few days duration does not develop after the injection of the vaccine and consequently the vaccinated person does not become more susceptible to typhoid fever during the negative phase

It is recommended that every year revaccination be carried out with a single dose of the vaccine

regurgitate or more commonly deposit the material by defecation Food contaminated in this way readily becomes the source of shigellosis

Water is another important source of shigellosis Shigellae may survive for a long time in untreated water Several water borne epidemics of shigellosis have been described The authors observed one such outbreak in a community of 7 000 people when the sewer broke into the water pipe line at the same time that chlorination failed

Milk may be contaminated during handling by carrier food handlers Pasteurization however readily kills Shigellae Water from a contaminated source used to wash bottles in a dairy may cause infection of the milk (Green and McLeod 1943)

PATHOLOGY

In the presentation of the pathology of shigellosis and in the discussion of its clinical symptoms the classical descriptions of Manson Bahr (1943) will be followed

Shigellosis causes acute or chronic changes in the intestines The pathology shows different degrees of severity Each of these may be accompanied by a specific clinical picture Exceptions from this rule however, are not very rare

The inflammatory changes are most often localized in the lower part of the bowel The rectosigmoid the descending colon the flexures and the cecum are frequently involved The lowest part of the ileum also may show pathology Round cell infiltrations hemorrhages necrosis with subsequent ulcerations and in chronic cases with fibrosis and hypertrophy are the basic features It is not clear as yet how much must be ascribed to the role of the excretion of absorbed toxins in the production of these changes A sympatheticotonic reaction of the intestine has been described by several authors

In acute cases the mucous membrane shows inflammation Hyperemia is present with dilated capillaries and veins This hyperemia of the follicles is characteristic in the beginning of the process Edema and hemorrhages follow chiefly in the submucosa Neutrophilic leucocytes and macrophages originating from the capillary endothelium of the bowel contribute to the infiltrates The capillaries show thrombosis Blood extravasation also occurs

As a result of these changes necrosis ensues Irregular snail track like' ulcers develop often on the summits of the mucosal folds These ulcers may be superficial or they may reach to the muscularis The size of the ulcers varies They often communicate by channels or sinuses The communicating channels may extend under the hypertrophic mucosa

Necrosis of the superficial layers may lead to the formation of diphtheroid pseudomembranes Or a necrotic mass may cover the entire intestine This mass is usually green or black due to altered hemoglobin and bile pigments When the pseudomembranes or the coagula fall off ulcerated surfaces become apparent In other cases much granulation tissue is seen

In fulminating cases the entire bowel is very *friable and much bleeding* occurs The lumen is obstructed with mucous and bloody masses

Children suffer very frequently from shigellosis The younger the child, the greater the danger of a fatal outcome of the disease Biocca (1941) found that in some states of Brazil 30 to 35 per cent of deaths in children under 2 years of age are due to shigellosis The statistics of Hormaeche et al (1943) confirm the frequency of this infection among children When we discount Shigella cultures received from the Armed Forces and isolated from veterans in our statistics children have been the source of more than 70 per cent of the Shigellae typed in this center

Army camps frequently suffer from shigellosis As Bargen (1945) points out such epidemics have occurred mostly during the period when the camp was being put into use and disappeared later when hygienic measures became firmly established

Shigellosis used to be a scourge of the armies The great epidemics of this disease during the South African War and the Gallipoli campaign discussed by Manson Bahr (1943) were not repeated in the second world war, due to the use of sulfonamides better sanitary conditions, and educational efforts

Persons suffering from other diseases such as malaria kala azar tuberculosis or malnutrition are more likely to contract shigellosis The same holds true of mental patients and old people Thousands of inmates of German and Hungarian concentration camps died from shigellosis superimposed over extreme malnutrition This condition was called the Ukraine diarrhea "

Shigellosis spreads readily among people living under crowded conditions as in some mental hospitals prisons and Indian bazaars where the rules of hygiene are not kept either because of weakened mental abilities of the inmates or because of the personal ignorance of the inhabitants

Carriers are very dangerous Only human carriers of shigellosis are known to date Convalescent carriers excrete Shigellae long after the dysentery has healed Many such carriers are intermittent carriers ' who excrete the organisms only during certain periods of time These are easily overlooked when the stool examinations are not repeated Inadequate treatment with sulfonamides or antibiotics unfortunately aids in producing a carrier state Symptomless carriers' and contact carriers have never to their knowledge shown symptoms of shigellosis Transitory carrier states are often observed in overcrowded hospitals or isolation wards where cases or carriers of different Shigella strains are congregated

About 3 per cent of persons who have suffered from shigellosis become chronic carriers *Sh sonnei* very frequently produces this condition while *Sh parad) senteriae* carriers are more often intermittent carriers The greatest danger of carriers arises when they are used as food handlers cooks waiters, dairymen packers in the food industry etc

Food is a frequent vehicle of shigellosis It may be contaminated not only by carriers but also by human excreta used as fertilizer

Manson Bahr (1943) first proved the role of the housefly in the propagation of shigellosis Houseflies may carry feces containing Shigellae on their wings legs or proboscides They may swallow infected feces and either

3 Fulminating dysentery, which includes the gangrenous and the cholera form subtypes
4 Relapsing dysentery
5 Chronic dysentery
6 Sonne dysentery

This classification will be followed in this chapter, except for the sequence of the forms

Catarrhal Dysentery

The onset is often slow In many cases, however, the beginning is sudden The first symptom is diarrhea consisting of frequent evacuation of the bowel Usually 3 to 12 stools are produced during the day These consist first of soft feces later becoming bilious and watery Their volume decreases Mucus is a characteristic ingredient of the stools

There is little or no fever The tongue is clean Prostration may be present

Cramps and straining are the chief complaints The griping is more severe when the lesions are nearer to the cecum while tenesmus predominates when the pathology is more extensive in the rectosigmoid Tenesmus, however usually develops only after several bowel movements

Vomiting is rare

This clinical form is most often due to *Sh sonnei Sh alkalescens* or *Sh ambigua*, rarely to *Sh paradysenteriae*

Shigella Food Poisoning

Shigellosis contracted by eating food contaminated with Shigellae may follow any of the several clinical forms of this disease In a number of cases however perhaps due to the toxins of Shigellae present in the food or as a sequela of the presence of some additional organism capable of causing food poisoning this clinical picture is observed

The onset is sudden in most persons who have participated in the infected meal

There is diarrhea with 4 to 15 stools a day The feces are light colored yellow or green Much mucus is present

The tongue is clean or coated There may be some fever Prostration is present

Cramps increasing into colic are always observed Griping pains are more frequent than tenesmus

Nausea and vomiting are regularly present

This clinical form is most often due to *Sh sonnei* or *Sh alkalescens* less frequently to *Sh paradysenteriae*

Sonne Dysentery

The onset is sudden or insidious In the latter case frequent bowel movements without discomfort introduce the disease The diarrhea consists of stools which are at first brown then yellow or green "Tomato soup" stools are often seen Mucus is always present in the feces

In a well developed shigellosis the intestine is edematous inelastic and contracted

Round cell infiltrations of the mesenteric lymph glands are very frequent

The spleen is congested The kidneys may show patchy glomerular congestion tubular necrosis and cloudy swelling A lymphoid peritonitis may accompany severe and fulminating inflammations

Perforations are very rare

Chronic shigellosis is a common disease but the diagnosis is frequently missed It is characterized by productive and ulcerative lesions Any of these two components may predominate The picture is frequently very colorful

The ulcers may be shallow or deep They do not have undermined edges The ulcers follow the direction of the mucosal folds They have dirty gray or brown bases The mucosa is swollen and often granular In some instances the entire mucosa is destroyed

Fig 153 —Section through colon in bacillary dysentery showing type of infiltration.

The fibrotic reaction is strongest in the mucosa and in the submucosa Scarring even stenosis may result

Pseudopolyposis is not rare

Manson Bahr s retention cysts are pseudoadenomata which cause jelly like elevations of the mucosa They may be disseminated over the entire intestine The retention cysts contain mucus and usually a large number of Shigellae Their presence causes frequent reinfections and the carrier state

Secondary infection or a double infection with Shigellae and *Endamoeba histolytica* may produce aberrant pictures

SYMPTOMATOLOGY

The incubation time is 1 to 10 days

Manson Bahr (1943) divided shigellosis into the following clinical forms

1 Mild dysentery the catarrhal form
2 Acute dysentery the classical bacillary dysentery

This type of shigellosis is caused by *Sh. dysenteriae*. Clostridia are thought to play a great role as secondary invaders.

Choleriform Dysentery

This is a fulminating shigellosis usually with a fatal outcome.

The course of the disease is characterized by subnormal temperatures, circulatory weakness and liquid offensive stools.

This type of shigellosis is caused by *Sh. dysenteriae*. We have observed it also in institutionalized old people. The etiologic agents were *Sh. dysenteriae* and *Sh. paradysenteriae*.

Relapsing Dysentery

Relapses of dysentery may occur in any clinical form. They are most often observed, however, in the classical type of shigellosis.

A new attack of dysentery develops when the patient has already begun to recuperate. Such relapses may last for variable lengths of time. Before the introduction of sulfonamides relapses were of varying severity. At present, however, the intensity and duration depend upon the medication. Relapses are often observed when too small doses are given or when the drug is discontinued too soon.

Chronic Shigellosis

Chronic shigellosis is one of the greatest problems of gastroenterology and much deserved attention is paid to it in contemporary literature. Manson-Bahr (1943), D'Antoni (1943), Silverman and Friedrichs (1943), Bargen (1945), and Felsen (1945) contributed much to the knowledge of the disease.

The clinical picture very often resembles amebic dysentery, or in some cases the sequelae—ulcerative colitis, "irritable colon," etc.—are prominent, and only bacteriologic, sigmoidoscopic and x-ray examination will reveal the real cause of the sickness.

The disease may begin as a chronic shigellosis per se, with an attack of diarrhea and in some cases fever. The stools may contain a varying amount of blood and mucus. This state may last, with shorter or longer remissions or intermissions, for a very long period of time.

In other cases the patient recuperates after an attack of acute shigellosis only to develop, after months or even years, a state of alternating diarrhea and constipation. The initial attack may have been so mild that it was overlooked.

In some instances diarrhea is scarcely present; rather, the patient has constipation. In these cases psychoneurotic symptoms may be prominent. There is fatigue, lassitude, inability to concentrate, morning headaches and alterations of the appetite. Abdominal discomfort with feeling of pressure or even pain along the descending colon and rectosigmoid, in the flexures or over the appendiceal region, may be present.

There may or may not be fever The tongue is clean or white Prostration is usually present

Cramps and colic griping pains and tenesmus may be present Griping pains are very frequent chiefly at the beginning of the illness

Nausea and vomiting are often observed

A respiratory catarrh is the characteristic feature of this clinical form of shigellosis The disease often begins with pharyngitis or bronchitis and the diarrhea appears only a few days later Catarrhs of the respiratory tract may dominate the clinical picture so that the diagnosis of an influenza attack later eventually modified with an *epitheton ornans* and called ' intestinal flu ' may be born

Epidemics of Sonne dysentery resembling 'intestinal flu' frequently occur in large cities An accumulation of such cases was observed in 1946 among children in Chicago

It must be emphasized that *Sh sonnei* infections often cause other clinical types of shigellosis

Classical Bacillary Dysentery

The classical type of shigellosis is classified by Manson Bahr as "acute dysentery "

The onset is usually sudden The disease however may begin as a single diarrhea without characteristic stools The diarrhea when fully developed is severe As many as 20 to 40 stools are evacuated each day They are first feculent then mucus and blood appear in them The mucus may be bile stained The amount of the feces decreases so that only small masses of viscid jelly like bloody mucus are evacuated These stools resemble ' red currant jelly or meat washings " The stools are odorless or have an albuminous odor If gangrene complicates the disease the stools become gray and are very offensive

Fever is usually present It does not usually exceed 103° F The face is flushed The tongue is white or coated Great prostration is present

The cramps and colic are severe There is straining griping pains and tenesmus are present according to the localization of the process

Vomiting is rather rare

Dysuria is frequent

Upon physical examination the abdominal muscles are rigid and make palpation difficult When they relax the contracted spastic colon may be felt

This clinical form of shigellosis is usually due to Sh dysenteriae Sh ambigua and Sh paradysenteriae

Gangrenous Dysentery

This is a fulminating shigellosis usually with a fatal outcome

It begins with chills The temperature is elevated and may reach 102° to 104° F Then diarrhea develops There are usually many green or gray offensive stools The abdomen is sunken and tender The tongue is thickly coated Pain cramps and tenesmus may or may not be present The disease lasts usually only a few days

swelling of the joints The knees and the ankles are the usual seats of this complication Organisms are not recovered from the exudates but these fluids readily agglutinate Shigellae

Eye Complications—Conjunctivitis frequently accompanies Shigella arthritis Conjunctivitis alone or with iridocyclitis is rather rarely observed It occurs only *in Sh dysenteriae infections*

Reiter s Syndrome—Reiter s syndrome consisting of an aseptic urethritis conjunctivitis and arthritis is considered by some authors a sequela of shigellosis

Other Complications—Peripheral neuritis and parotitis are often mentioned as possible complications and sequelae of shigellosis They are very rare

SIGMOIDOSCOPIC FINDINGS

The sigmoidoscopic appearance of shigellosis was described in great detail by Manson Bahr (1943) and Felsen (1945)

At first small elevations with or *without a yellowish apex are observed* Then small ulcerations ensue which spread and coalesce The ulcers are irregular in size shape and extent They are not very deep

The mucosa is inflamed and reddened The entire mucosa may show inflammation Later edema appears often followed by bleeding and pus formation

In the pseudomembranous type the membranes may be seen A bleeding uneven granular surface lies under the membrane This surface is often covered with pus Frequently only remnants of the membrane resembling strings or threads are seen

Regeneration is characterized by the formation of granulation tissue The mucosa remains reddish pink for a long time *After healing* a pitted mucosa is frequently seen

The sigmoidoscopic patterns of chronic shigellosis were classified by Manson Bahr as

1 Superficial ulcerations
2 Granular mucosa
3 Generalized mucoidal inflammation with deep involution of the bowel wall

There is great irritability of the rectosigmoid during shigellosis It is recommended therefore that sigmoidoscopic examinations be carried out only by proctologists or physicians with considerable experience in the handling of this instrument

X RAY EXAMINATION

The x ray picture of shigellosis has been mentioned *in Chapter 4* Due to the acute course of most cases of shigellosis not much material is available for such studies Bargen (1945) called attention to the irregular and yet extensive distribution of Shigella ulcers which may be observed by studies of the mucosal pattern of the bowel

Complications and Sequelae

It is sometimes difficult to draw a dividing line between complications and sequelae They are therefore discussed under the same heading

Ulcerative Colitis—Ulcerative colitis with a chronic course is a frequent sequela of shigellosis The transition is usually slow and gradual In many cases however the beginning of the ulcerative colitis is severe The sigmoidoscopic picture and the course of the disease do not differ from those observed in the so called nonspecific ulcerative colitis originated by other factors Felsen (1945) made excellent contributions to this subject

Regional Ileocolitis—Regional ileitis and colitis may be caused by bacillary dysentery This sequela is relatively rare

Deformities and Hypertrophy of the Colon—Narrowing of the lumen is a frequent sequela of deep ulcerations Stenosis may also develop Megacolon is infrequent Into this group belong prolapse of the rectum and polyposis While prolapse is more often observed in children polyposis is more frequent in adults

Nutritional Disturbances—Many patients suffering from chronic shigellosis become sensitized against certain foods chiefly against milk and eggs Such allergies must be kept in mind when the patient s diet is compiled

Nutritional deficiencies are more frequent in shigellosis than is commonly thought There is an impaired absorption of members of the vitamin B group The metabolism of vitamin K is also frequently disturbed

Nutritional deficiencies may become very severe The walking skeletons of the tropics are frequently the results of Shigella infections

Functional Disturbances of the Digestive Tract—The formation of several digestive enzymes may be impaired Dyschlorhydria usually in the form of hypochlorhydria is common

Mucous colitis is very frequent A so called irritable colon is observed in most cases of chronic shigellosis and may appear in any patient as a sequela of an acute shigellosis

Ascites is not rarely seen in India following shigellosis This sequela is very rare in the Americas

Perforation—Perforation of the bowel rarely occurs in shigellosis The symptoms are those observed in perforations due to other diseases

Urogenital Apparatus—Shigella pyelitis has been observed Pregnant women seem to be more frequently attacked by this form of shigellosis than other members of the general population (Haynes et al 1941 and Biddle and McKee 1942)

Pyelitis cystitis and urethritis caused by other bacteria are not infrequent complications of shigellosis

The kidneys are under great stress during the disease In many fatal cases death occurs as a result of renal insufficiency

Arthritis—Arthritis is observed only in *Sh dysenteriae* infections It usually develops during the period of convalescence There is fever and

30 000 cells The number of white blood cells decreases during the further course of the disease

Anemia develops in severe shigellosis *Due to the dehydration the number* of red blood cells may remain normal even in such cases

DIFFERENTIAL DIAGNOSIS

The only decisive factor for the diagnosis of shigellosis is the cultural proof of the presence of Shigellae in the feces When however the patient has been given sulfonamide therapy before a sample is taken for laboratory examination the bacteriologic diagnosis is greatly endangered Except under the most primitive conditions one cannot find any excuse for omitting such an examination Modern preserving fluids and present day transportation facilities permit the delivery of a fecal sample to a laboratory *in most* cases

The bacteriologic examination may be more difficult in chronic bacillary dysentery As Manson Bahr (1943) pointed out it is extremely difficult to recover Shigellae from a chronic dysenteric granulosis of the rectosigmoid When ulcerative colitis has developed the organisms are rarely found

Bacteriologic and parasitologic examination will differentiate amebiasis *giardiasis salmonellosis schistosomiasis tuberculosis and other infections* Inguinal adenitis and a positive Frei test are characteristic for lymphogranuloma venereum Blood examination will exclude malarial dysentery Positive serologic tests characterize syphilis of the bowel Intestinal actinomycosis is rare and usually shows different lesions when examined sigmoidoscopically

A diagnosis of sprue must be made from the appearance of the stools flat glucose tolerance curve a steatorrhea and typical x ray picture

*A carcinoma of the rectosigmoid may cause considerable diagnostic diffi*culties The sigmoidoscope and the x ray are the most potent aids in establishing the presence of this neoplasm

Diverticulitis intussusception foreign bodies hemorrhoids thyrotoxicosis uremia poisoning with mercury and arsenic also must be considered when the diagnosis of shigellosis is made

PROGNOSIS

The over all mortality of shigellosis is 4 to 5 per cent It is higher in children and in older people The prognosis is grave in fulminating forms *Sh dysenteriae* infections formerly caused mortality rates as high as 25 to 50 per cent before the advent of the sulfonamides At present the fatality rate is considerably lower

Manson Bahr (1943 1945) calls attention to the necessity of watching the stools the tongue and the pulse during shigellosis because *the prognosis* is based upon observation of these conditions

LABORATORY EXAMINATION

Stool Examination

Shigellae are only exceptionally isolated from the blood and from the urine The examination of the stools is therefore the only available means for detection of these organisms

Many Shigella strains are fastidious Nonselective and medium-selective plates must be used for this reason The SS agar (Difco) and DEC plate of Panja and Ghosh the DCLS medium (Baltimore Biological Laboratory) MacConkey s plate and eosin methylene blue agar are most often inoculated Several plates should be streaked with each specimen or when the results are negative the examination should be repeated

An excellent method to collect material is the rectal swab technic devised by Hardy et al (1942) See Chapters 71 and 72

The colonies isolated on the diagnostic plates are identified according to the procedure described in Gradwohl *Clinical Laboratory Methods and Diagnosis* vol 2 1948

Agglutination Tests

Agglutination tests using the patient s serum and antigens prepared from Shigellae are of little value Hulst (1940) Draper (1945) and others proved that so called natural agglutinins may be present in healthy individuals On the other hand agglutinating bodies develop late in the disease usually during the second or third week when the diagnosis has already been easily established by stool examination Their titers are frequently low Agglutination with serum dilutions 1 100 and higher are usually considered positive Many cross reactions are observed with paracolon organisms and other bacteria The value of the agglutination test is therefore very problematic

Cytology of the Stools

Much attention should be paid to the cellular composition of the stools Red blood cells and polymorphonuclear leucocytes are often present Macrophages with remnants of engulfed cells and cell fragments are frequent They are readily mistaken for amebae except in hematoxylin stained preparations There is much debris present It must be pointed out that in catarrhal shigellosis the number of cells may be very small Mucus is however always present

Young leucocytes and macrophages are numerous when ulcerations are forming Their number diminishes during healing At the end of the disease old leucocytes with pyknotic nuclei and numerous epithelial cells dominate the picture The cellular elements are often embedded in streaks of mucus

Hematology

The peripheral blood does not show great changes In the beginning chiefly in severe cases however there may be a leucocytosis with as many as

Insufficient urinary output is a contraindication for sulfonamide medication

It is good practice to begin the treatment of acute toxic shigellosis with 5 to 6 Gm of sulfadiazine divided into 5 or 6 doses during the first day then 3 Gm of sulfaguanidine *or* 4 Gm of sulfasuxidine *or* 2 Gm of Sulfaphthalidine every 4 hours until the number of stools is 4 or less per day finally the same amount of the selected sulfonamide 3 times a day until the stools become normal for 2 days

In cases which do not show toxic symptoms 3 5 Gm of sulfaguanidine or 5 Gm of sulfasuxidine *or* 2 Gm of Sulfaphthalidine are given 4 times a day until the stools become normal for 2 days

In chronic cases 0 5 Gm of sulfadiazine *and* 2 Gm sulfasuxidine 4 times a day for 14 days the course repeated after 14 days intermission has proved beneficial Good results have also been seen by giving 1 Gm Sulfaphthalidine 4 times a day for the same periods of time

Recently phthalyl sulfacetimide (Thalamyd) has been introduced in the treatment of shigellosis This drug is only very slightly absorbed but it penetrates the intestinal mucosa It has proved very effective in the therapy of bacillary dysentery ulcerative colitis and cholera Adults receive 6 to 9 Gm daily children 0 2 Gm per kilogram body weight per day

Vaccine Therapy

Vaccine therapy is recommended in chronic shigellosis Autogenous vaccines are used Berge and Fauconnier (1941) recommend this treatment

Bacteriophage

Soesman (1941) McKay (1943) and Burke (1944) recommend this therapy Boyd and Portnoy (1944) and Morton and Engley (1945) reject it It is little used in the Americas The bacteriophage is given orally or per rectum 2 c c daily

Dietary Treatment

During the acute stage of dysentery an easily digested high caloric diet rich in *vitamins and low in residue is given*

The fluid intake must be 4 to 6 liters a day Weak tea rice water and soups are recommended Fruit juices are not always well tolerated Orange Crush may be tried Lactose or sucrose is added to the fluids to increase their caloric value

It is advisable to give only fluids during the first and second days of the disease The diet is supplemented later with jellies and egg yolk Amino acids *usually 2 teaspoonfuls 3 times a day are beneficial*

When gross bleeding has stopped puddings custards chocolate and malted milk butter, toast crackers well cooked rice and tapioca are added

In chronic dysentery the diet described under 'Amebiasis will render excellent service

TREATMENT*

Fluid Intake

The most important part of the therapy is to assure an adequate intake o fluids. The daily urinary output *must* be kept above 1,500 c.c.

If a proper urinary output cannot be achieved by oral administration in fusions with 5 per cent glucose are recommended. As much as 4 liters can b given daily. The average dose is 2 to 3 liters per day.

Serum Therapy

Forty to 50 c.c. of specific or polyvalent serum are given intravenousl twice a day in 250 to 500 c.c. of physiologic saline. The serotherapy must b begun early. There is no need to give serum during the later days of th disease.

The serotherapy must be limited to toxic cases. Because of the larg amounts of serum necessary to combat the symptoms, desensitization is nece sary prior to the injections.

One hundred fifty to 200 c.c. of convalescent serum or plasma give goo results.

Whole blood (250 to 500 c.c. daily) is very beneficial in toxic cases.

General Measures

It is very important that every patient with an acute shigellosis or wit an attack of a recurrent chronic dysentery remain in bed.

The patient must be kept warm.

Sulfonamide Drugs

The critical evaluations of sulfonamides in dysentery by Lyon (1941 Hardy et al. (1943), Bose et al. (1945) and Bargen (1946) show that a dru must be chosen according to the case and that the patient and *not* the disea must be treated. Hardy et al. (1943) and Woodrow and Douglas-Henr (1945) recommended sulfadiazine. Bulmer and Priest (1942), West (1943 Fairley and Boyd (1943), Page (1944) and Yannet et al. (1944) were satisfie with sulfaguanidine. Kuhns (1943), Manson-Bahr (1945) and Bargen (194 recommended a choice between sulfaguanidine and sulfasuxidine, the latt being less toxic but perhaps also less active. Streicher (1945) had exceller results with Sulfaphthalidine which is now being used on a larger scale.

Sulfonamide drugs must not be given for a longer period than 14 day During the treatment frequent urine examinations must be carried out and th drug discontinued whenever an excess is present in the urine. Period hematologic examinations are also indispensable to avoid damage to th hematopoietic system.

Two to 4 Gm. of sodium bicarbonate must be given with each dose o sulfonamide drugs.

---

*Recently antibiotics, aureomycin, Chloromycetin, terramycin and neomycin per os ha been recommended.

stools with the aid of the Hardy swab or through the proctoscope and also to examine postcathartic fecal specimens because of the varying sites of the lesions

A carrier must be checked at least for 3 months before release During this period at least 6 stools must be examined

Carriers of *Sh sonnei* are frequently refractory to sulfonamide medication Changing from one drug to the other is recommended in such cases

There is little use in examining the stools for Shigellae during sulfonamide treatment because the medication may inhibit the growth of Shigellae on diagnostic plates The first release specimen must not be taken earlier than 1 week after the sulfonamide administration has been discontinued

Carriers often require prolonged sulfonamide treatment It must be kept in mind that this medication also reduces the number of organisms which are necessary for certain normal physiologic functions of the bowel Care must be exerted therefore to avoid both sulfonamide intoxication and nutritional disturbances

PROPHYLAXIS

General rules for the extermination of shigellosis may be summarized as

1 Control of Carriers

No food handler harboring and excreting Shigellae shall be allowed to handle or prepare food Repeated stool examinations before and during employment are necessary to detect carrier food handlers It is important that not only food handlers in the usual sense (waiters cooks cowhands dairy workers food packers etc) *be examined but also nurses and maids who nurse* and feed children

2 Food Control

Shigellae pathogenic for man do not occur in animals the meat milk or eggs of which are used for human consumption Protection of food from infection by human carriers flies and contaminated water will therefore keep food free from Shigellae

3 Water and Sewage

Water borne shigellosis is more frequent than is generally thought The water may *be contaminated with sewage either by seepage or by direct* evacuation of such material into it

Chlorination or boiling destroys Shigellae promptly

4 Flies

Flies are dangerous vectors of shigellosis One of the most efficient measures in the campaign against shigellosis is screening or other methods which keep flies away from food

5 Vaccination

Much progress has been made in vaccination against shigellosis during *the last years As Weil and Farsetta (1944 1945)* proved the specific anti

Intestinal Absorbents and Aperients

Kaolin and its combinations as Kaopectate Kaomagma etc are helpful for the absorption of the toxins These are indicated during the diarrhea or when much flatulence is present If absorbents are given, the sulfonamide medication must be timed in such a way that these drugs are not absorbed (and thus inactivated) by the kaolin

Many authors advocate the use of aperients before treatment As Manson Bahr (1943 1945) points out saline cathartics must not be given in dehydrated cases because they cause further loss of water One tablespoon (4 Gm) of sodium sulfate in about 150 to 200 c c warm water is the best cathartic in constipation during chronic dysentery

Relief of Pain

Heat is essential in the treatment of dysentery Dry hot pads or pillows placed on the abdomen relieve pain and cramps Short hot baths are also useful

Lavages with 0 1 to 0 2 per cent potassium permanganate may be used in cases with pseudomembranes Washings of the bowels with 1 5 per cent tepid boric acid serve the same purpose

Opium morphine and papaverine render excellent services in the treatment of acute shigellosis They may be given in injections in enemas or in suppositories It is recommended that these drugs be combined with belladonna A small dose of barbiturates may be added

℞ Tinct opii 30 min
Tinct belladonnae 10 min
Elix phenobarbitur 20 min
Starch and water q s ad 2 oz
S Enema

℞ Papaverin sulf 0 3 Gm
Atropin sulf 0 002 Gm
Ol Cacao q s u ft suppos no 10
S One suppository 1 3 times a day

Treatment of Complications

Ulcerative colitis is treated with sulfonamides dietary and other measures used in that disease if caused by other factors

The prognosis of ulcerative colitis *quoad sanationem* is not favorable If surgical treatment is advised Manson Bahr (1943 1945) favors appendicostomy

Nutritional disturbances are treated with proper diet and injections of vitamins

Sulfonamide drugs and heat are recommended in arthritis and in eye complications

Treatment of Carriers

The sulfonamide treatment of carriers must be planned as in chronic shigellosis In order to be able to check the results of this therapy several stool specimens must be examined It is of paramount importance to collect

gens which are different for each type of Shigella play a great role in immunity Because of the great number of types it is very difficult to produce polyvalent vaccines In addition Shigella vaccines cause severe reactions

Morgan and Partridge (1941) used alkali treated material for immunization Halbert et al (1945) reduced the toxicity of the antigens by injecting saline in mineral oil emulsions Treffers (1946) found that acetylated antigens are less toxic Olitzki and Koch (1945) worked out a special method for the production of effective antigens

While whole organisms or their extracts are used for vaccination against *Sh paradysenteriae* *Sh ambigua* and *Sh sonnei* formolized toxin (toxoid or anatoxin) is injected very often for the protection against shigellosis caused by *Sh dysenteriae* the only member of the genus which produces a true toxin

Olitzki and Koch (1945) Farrell (1943) Anderson et al (1945) and Dubos and Geiger (1946) recently made considerable contributions to the technic of the preparation of *Sh dysenteriae* toxoid Farrell et al (1944) has had good experiences with it in human volunteers Olitzki and Koch (1945) have observed excellent results in a great number of exposed persons

Experiments on volunteers with vaccines were performed by Morgan and Schutze (1943) and Goebel et al (1945) Cooper et al (1944) immunized children with a *Sh paradysenteriae* vaccine and found that intravenous injections cause the greatest elevation of mouse protective antibodies Forsyth (1942) and Felsenfeld and Young (1945) prepared mixed vaccines against *Sh dysenteriae* and *Sh paradysenteriae*

Proper hygienic measures and the encouraging results of sulfonamide treatment have greatly reduced the necessity for antishigellosis vaccination Such vaccination is still advisable however Toxoid injections and during epidemics vaccines prepared from the strains which cause the outbreaks are indicated in the tropics

Prophylaxis with the aid of dysentery bacteriophage is recommended by Dumesh (1942 but is rarely used in the Americas

6 Drug Prophylaxis

Sulfadiazine or Sulfaphthalidine 0 5 Gm twice a day are said to be effective for the prophylaxis of shigellosis

SALMONELLOSIS IN CHILDREN

Hormaeche and Peluffo define salmonellosis as "an infectious contagious disease which presents all the characteristics and manifestations of a true infection, with progressive development, variety of localizations and high mortality."

The immunology, epidemiology and bacteriology have been discussed in Gradwohl (1948).

Biochemical characteristics routinely used in identifying Salmonellae do not easily differentiate them from paracolons, which are "slow" fermenters of lactose and sucrose. Paracolons also seem to occupy an important position in pathology; they have frequently been isolated from cases of acute enteritis. Curbelo Hernandez, Soto Pradera and Montalvo Urrutibeascoa reported (1945) an outbreak of gastroenteritis due to paracolons among newborn infants.

BACTERIOLOGIC EXAMINATION OF SALMONELLOSIS BY CULTURE

The following method is used by us for fecal material.*

When the samples are to be sent from a distance, the Teague and Clurman mixture is used. (This is a sterile 30 per cent buffered glycerin in saline solution.) A fresh feces specimen or, better, mucus, pus, or blood when available, is inoculated in an enrichment medium (selenite F or tetrathionate broth) *as well as seeded directly, after* previous washing, on such media as SS agar and MacConkey agar. All are incubated for 18 to 24 hours. From the enrichment medium, seedings are made in SS agar and MacConkey agar.

Tetrathionate broth, SS agar, and MacConkey agar are considered excellent. Suspected *colonies are transferred to tubes of plain broth containing* the sugar series. If the

Photographs in this chapter are from autopsies made during an epidemic outbreak of meningitis in the newborn by *Salmonella havana*. Studies made by Angel A. Aballi and collaborators in the Municipal Children's Hospital in Havana. (*21 cases*)

organism is gram negative, motile, produces acid and gas in glucose,* mannitol, maltose, and sorbitol, does not produce indol nor ferment lactose, it is suspected of belonging to the genus Salmonella. Serologic identification is too complicated for routine hospital laboratory use. The agglutination tests for antigenic analysis can be made in Salmonella Centers† or in well equipped laboratories with experienced personnel.

Where proper equipment is lacking and there is no Center available for the necessary service, pediatricians must be guided solely by the characteristics of the genus.‡

Blood Culture.—Blood culture is very important as an early step in the isolation of strains of Salmonella with great invasive power. Blood cultures are often positive, while the feces are negative.

Salmonellae in Cerebrospinal Fluid.—Salmonellae are present in the cerebrospinal fluid in cases of Salmonella meningitis. Twenty-one cases of meningitis in the newborn were studied in this hospital by Curbelo and Martinez Cruz. In 1940 Guerra Peluffo and Aleppo reviewed the literature and collected 56 cases of meningitis due to Salmonella. Seter later compiled 22 cases. The species most frequently found were *S. schottmuelleri* 8 cases, *S. typhimurium* 17, *S. choleraesuis* 5, *S. enteritidis* 34, and 13 cases were of a heterogeneous group of species (*havana, dublin, eastbourne, jena,§ london*). In Cuba, Valledor et al. reported a case of meningitis due to *S. eastbourne* which was cured by sulfapyridine and sulfadiazine.

Salmonellae may also be isolated from cultures of urine, pleural fluid, peritoneal fluid, etc.

FREQUENCY

Incidence of the different types of Salmonellae may vary in different countries and even in different localities in the same country. See Chapter 29.

CLINICAL SYMPTOMS

The majority of our cases in children during the early days of their lives have been caused by a septicemic type with extraordinary intensity of infectiveness and have almost constantly been accompanied by meningoencephalitic symptoms and high fatality. During the first years of life, it is possible to observe diarrheal forms of mucogranulous or purulent mucohemorrhagic type constituting the most marked symptomatology and therefore confused with dysenteric affections in such infants.

Other cases are manifested as pyretic gastroenteritis with a typhoid pattern, and only bacteriologic investigations can establish their true nature. It is interesting to note that the choleriform syndrome may appear frequently in these cases, either as a dyspeptic type, "toxic dyspepsia," with intense dehydration, or as an episode within one of the forms indicated above, generally leading to a fatal disturbance of the acid base balance. On other occasions we have been able to verify the marked neurotropic tendency such as occurred in our epidemic of 1936. We have observed localization also in the respiratory apparatus in more or less severe form, sometimes causing fatal bronchopneumonia.

At times the septic picture is accompanied by visceral rupture which affects widely separated sites, or forms may be accompanied by arthritis and

*Exceptions are listed on page [illegible].

†Credit should be given to P. R. Edwards, the pioneer in Salmonella Centers, who contributed so much to the knowledge of salmonellosis. (O. F.)

‡Divergent opinion is to be found in Chapters [illegible] and [illegible] of this book and in Craigwohl (1948).

§[illegible] (O. F.). Not considered a species per se today.

In severe cases vitamins B_1 and C are administered during the early stages and later factors of the B complex and liver extract are injected intramuscularly In older children the first food should be fruit juices Four or five days later they may be given boiled chicken or fish and skimmed milk Regular diet was occasionally begun ten days after commencement of the diarrhea

In undernourished children blood transfusions and infusions are administered if necessary to correct dehydration

Symptomatic treatment is indicated at times tincture of paregoric is used against tenesmus and diarrhea Stimulants such as adrenalin and Coramine are given in syncope

Treatment with sulfonamide drugs combined with dietary and symptomatic medication is the classical treatment Agustin Castellaños published studies of major interest on this subject Insoluble forms of the drug (sulfaguanidine sulfasuxidine) are of little value in salmonellosis although these drugs are useful in shigellosis Salmonellae enter the body by way of the mouth and cause inflammatory lesions in the digestive tract The bacteria have a tendency to spread throughout the body by way of the blood stream and to localize extraintestinally Therefore according to Castellaños soluble sulfonamide drugs are to be used in treating the disease These drugs are easily absorbed and high concentrations can be reached in the blood, they act upon the bacteria not only in the intestines but also in the blood and remote organs Experimental and clinical studies dealing with the question indicate that *S choleraesuis* is greatly affected by soluble sulfonamide drugs It is possible that some serious cases caused by *S enteritidis* and *S typhimurium* may also react to these drugs According to clinical observations paratyphoid A does not seem to be affected by the soluble sulfonamide drugs although experimental studies indicate that it is susceptible to them Administration of the soluble drugs does not influence the clinical course in paratyphoid B and C infections in man In the opinion of Zerbino et al the use of sulfonamide drugs in Salmonella enteritis is efficacious when a diffusing agent is indicated Sulfathiazole (Zerbino et al) has reduced mortality from 40 per cent to 7 1 per cent

Castellaños places sulfadiazine first among the sulfonamide drugs because it is less toxic and is better tolerated sulfathiazole is placed next and then other drugs which are absorbed

The patient shows clinical improvement within 24 to 72 hours if the sulfonamide drug is effective If no improvement is noted at the end of this period another sulfonamide drug is substituted This rotation sometimes gives excellent results When lack of tolerance is indicated (vomiting) the drug may be administered parenterally intramuscularly, or intravenously as the case may require (Castellaños) In chronic cases an autogenous vaccine is indicated (Castellaños) Drugs with localized action give uncertain results

In infections due to a combination of bacteria—Shigellae associated with one or more types of Salmonella or several types of Salmonellae together—a soluble sulfonamide drug by itself will suffice *

*It is interesting to note that antibiotics are less active in Salmonellosis in children than in adults

osteomyelitis secondary anemia and even a hemorrhagic syndrome such as we had occasion to observe at an autopsy in 1936

Aballi divides salmonellosis in children into the following clinical types (1) slight digestive upset with dyspeptic syndrome (2) enterocolitis very frequently with dysenteric syndrome (3) toxic form of the infantile cholera type (4) septic form with typhoid pattern (5) neurotropic septicemia in the newborn and (6) septic form with tendency to varied localizations

The hemogram in salmonellosis may show transient leucopenia with relative lymphocytosis Later this leucopenia is superseded by leucocytosis the intensity of which depends upon the clinical course of the disease and the complications

THE WIDAL SEROREACTION IN SALMONELLA INFECTIONS

Positive agglutination reactions may be observed in patients with Salmonella infection Cross reactions however do occur Differentiation may be attempted by repeating the test every two or three days, since the agglutinins continue to increase in titer against the specific bacterium which is causing the infection In extraintestinal Salmonella infections the bacteria at times cannot be isolated from the feces, but the serum of the patient nevertheless agglutinates the organisms at very high titers

Occasionally the serum of patients infected by Salmonellae shows lack of agglutinin O titer or a very low titer for O but the agglutinins for ' H may be high these may be formed exclusively against one of the phases *

TREATMENT

Zerbino writes that 50 per cent of cases of enteric infection in Uruguay are of specific enteritis (Shigella or Salmonella) His experience was with 384 children up to 2 years of age three fourths of whom were less than one year old Aballi Jr and J A Martinez Cruz indicated that in Cuba specific enteric infections are the most frequent cause of diarrhea in well nourished children Their figures were taken from private patients (116 cases) In his work Acute Diarrhea in Infancy and Childhood Aballi (1944) suggested the following plan of treatment Except in very mild cases a period of starvation should be allowed This helps control the symptoms rapidly In cases with severe vomiting nothing is given by mouth otherwise water or tea is given For babies the quantity of liquid is 3 ounces per pound of weight every 4 hours A mixture of sodium chloride and sodium bicarbonate helps prevent the upset of the acid base balance After improvement of the diarrhea a mixture of agar and pectin is used for 12 to 36 hours This is followed by acidophilus milk After 24 to 48 hours if it is well tolerated the amount of food is increased to cover the caloric requirements

Patients on a protein free diet over a long period must be given transfusions of whole blood and plasma to prevent hypoproteinemia

* See also Chapter 78

large, pale colored mass, composed of histiocytes, some uninuclear cells, other cells with nuclei in mitosis, the majority in a state of active phagocytosis Typhoid bacilli, if present, may be seen in the cytoplasm of the macrophages They do not exhibit the delicate appearance of the bacilli from cultures, but appear as long, rod like organisms, swollen and deformed

In the usual lesions of typhoid, it is very difficult to find bacilli unless death has occurred only a few hours ago thus facilitating the growth of *S typhosa*

Fig 16? —*Left* follicular colitis *right* follicular ulcerative colitis.

Not all macrophages survive the lethal action of the toxins of the engulfed bacilli Necrosis of the cells and of adjacent tissue results, this is a typical lesion in the disease Lymphatic and blood capillaries are seen blocked by large masses of macrophages and precipitated fibrin, this thrombosis interferes with the nutrition of the tissues, thus promoting the lethal effects of the bacterial action Capillary obstruction by itself, however, is not considered responsible for the necrosis

The final result of this process is the transformation of normal lymphatic follicles of the intestinal mucosa into enlarged corpuscles of a soft, succulent consistency, this condition is found in masses of necrotic tissue which *is gray* or yellowish gray, sometimes hemorrhagic

The necrotizing process is extensive and involves the surrounding tissue, with intense ulceration of the mucosa, followed by secondary infection with in

PROGNOSIS

Prognosis is related to the age of the child The type of Salmonella is also important those belonging to group C of the Kauffmann White schema being extraordinarily malignant (Saphra)

PROPHYLAXIS

See Chapter 29

TYPHOID FEVER IN CHILDREN

Typhoid fever is an acute infectious disease caused by *Salmonella typhosa (Eberthella typhosa)*, which was discovered in 1880

That it may be transmitted from mother to fetus was first demonstrated by Eberth in 1889 (fetal or congenital typhoid) Typhoid fever in children presents certain individual features which distinguish it from typhoid fever in adults Rare in nurslings it becomes increasingly frequent as age advances This is due not to lesser susceptibility on the part of babies but rather to less opportunity for contagion It is found only exceptionally in breast fed infants although we had the opportunity of observing one case in an 8 month old child in a strongly infected area

Typhoid fever is found in all countries While absent in some regions in others it is endemic in character In tropical countries it predominates during the rainy season In general it increases in summer and decreases in winter In the temperate zones it is more frequent in autumn and early winter

PATHOLOGIC ANATOMY

Lesions of the tissues due to the typhoid bacillus involve principally the cells of the reticuloendothelial system—macrophage cells—plasma cells and lymphocytes Consequently the lymphoid tissue of the whole organism especially in the path of the primary invasion shows the most typical changes

Lesions outside the reticuloendothelial system develop secondarily often as a result of the combined action of the bacteria and physicochemical agents It is to be recalled that S typhosa is a gram negative bacillus with a complex flagellar cover It is capable of producing a strong endotoxin which is responsible for the general intoxication characteristic of the disease

Typical specific lesions in typhoid are definitely the result of the action of multiple factors

When the typhoid bacillus appears in the intestinal mucosa it is attacked by macrophages as a result of proliferation of the mucosal reticulum and that of the lymphatic follicles These cells envelop the bacilli even though the cytoplasm of such cells contains other dead cells living organisms fragments of leucocytes and lymphocytes plasma cells or red cells The engorged macrophages wander in and out of lymphatic and capillary channels and invade the neighboring lymphoid tissue

Constant proliferation of enlarged mononuclear cells occurs there is invasion of the lymphatic follicles this structure is eventually converted into a

large, pale colored mass, composed of histiocytes, some uninuclear cells, other cells with nuclei in mitosis, the majority in a state of active phagocytosis Typhoid bacilli, if present, may be seen in the cytoplasm of the macrophages They do not exhibit the delicate appearance of the bacilli from cultures, but appear as long, rod like organisms swollen and deformed

In the usual lesions of typhoid, it is very difficult to find bacilli unless death has occurred only a few hours ago, thus facilitating the growth of *S typhosa*

Fig 167—*Left* follicular colitis *right* follicular ulcerative colitis.

Not all macrophages survive the lethal action of the toxins of the engulfed bacilli Necrosis of the cells and of adjacent tissue results, this is a typical lesion in the disease Lymphatic and blood capillaries are seen blocked by large masses of macrophages and precipitated fibrin, this thrombosis interferes with the nutrition of the tissues thus promoting the lethal effects of the bacterial action Capillary obstruction by itself, however, is not considered responsible for the necrosis

The final result of this process is the transformation of normal lymphatic follicles of the intestinal mucosa into enlarged corpuscles of a soft, succulent consistency, this condition is found in masses of necrotic tissue which is gray or yellowish gray, sometimes hemorrhagic

The necrotizing process is extensive and involves the surrounding tissue, with intense ulceration of the mucosa followed by secondary infection with in

testinal bacteria Deep seated lesions, such as those of mesenteric glands, spleen liver, and bone marrow, undergo liquefaction If the patient survives the infection, these deep seated lesions heal by cicatrization or partial reparation of the destroyed tissue

If extensive necrosis or secondary infection is present, the cellular reaction is complicated by the appearance of polymorphonuclears although mononuclears continue to predominate These determine the morphologic character of the reaction Notwithstanding the fact that typical lesions may develop on a large scale in areas where there are large numbers of reticuloendothelial cells a typhoid lesion or granuloma may develop in any tissue of the system because of the specific nature of the lesions

Fig 163—Left ulcerohemorrhagic colitis right, pseudodiphtheritic colitis.

The macroscopic and microscopic characters of the granuloma differ in various organs, due to the difference in structure of the organs Lesions of the separate tissues are

Digestive Tract —Localization of lesions in the digestive tract is determined entirely by the distribution of lymphoid tissue In severe cases acute ulcerative lesions may develop in the mouth and in the pharynx When these lesions are secondarily infected large diffuse pseudodiphtheritic areas of the mucosa are formed The secondary infection conduces to the formation of large retropharyngeal and peritracheal abscesses, accompanied by necrosis of

the laryngeal tissue and by chondritis of the laryngeal and tracheal cartilages The epiglottis is not affected since it is not composed of lymphoid tissue Lesions in the mouth and in the pharynx reside in the lymphoid tissue as described above appearing first as local enlargements which ulcerate and rapidly become subject to secondary infection

The esophagus usually does not show any alterations The stomach on rare occasions presents mild, round ulcerations with a necrotic center These are situated in the lymphoid tisue They are elevated swollen greenish yellow in color with notched border

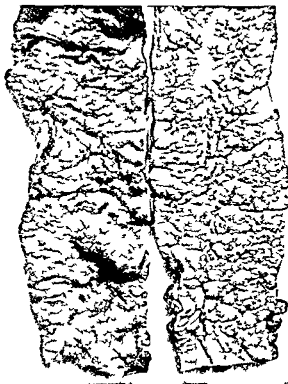

Fig 164 —Polypoid diphtheroid colitis

Although ulcerative lesions sometimes are found in the duodenum typhoid lesions in this part of the digestive tract are rarer than in the stomach Lesions are scant in the small intestine in the upper part as well as in the lower part of the jejunum They increase progressively in number and in size in the ileum as they approach the ileocecal valve since in this portion lymphatic formations known as Peyer s patches are more abundant

At autopsy of patients who have died of typhoid fever during the second or third week of the disease all of the successive stages of development of typhoid lesions can be seen These range from simple hyperemia and edematous enlargement of the small lymphatic follicles to confluent lesions with ulceration and hemorrhage Where the lesions are isolated they are found situ

testinal bacteria Deep seated lesions such as those of mesenteric glands spleen liver, and bone marrow undergo liquefaction If the patient survives the infection these deep seated lesions heal by cicatrization or partial reparation of the destroyed tissue

If extensive necrosis or secondary infection is present the cellular reaction is complicated by the appearance of polymorphonuclears, although mononuclears continue to predominate These determine the morphologic character of the reaction Notwithstanding the fact that typical lesions may develop on a large scale in areas where there are large numbers of reticuloendothelial cells a typhoid lesion or granuloma may develop in any tissue of the system because of the specific nature of the lesions

Fig 163 —Left ulcerohemorrhagic colitis right pseudodiphtheritic colitis

The macroscopic and microscopic characters of the granuloma differ in various organs due to the difference in structure of the organs Lesions of *the separate tissues are*

Digestive Tract—Localization of lesions in the digestive tract is determined entirely by the distribution of lymphoid tissue In severe cases acute ulcerative lesions may develop in the mouth and in the pharynx When these lesions are secondarily infected large diffuse pseudodiphtheritic areas of the mucosa are formed The secondary infection conduces to the *formation of* large retropharyngeal and peritracheal abscesses accompanied by necrosis of

yellowish white areas of necrosis Occasionally large necrotic areas of infarcts may be observed in the spleen Histology is similar to that observed in the lymphatic glands

Liver—The liver is increased in size swollen of a reddish gray color sections appearing congested with necrotic areas which are not constant but which are uniformly distributed They cannot be seen easily macroscopically but can be seen readily in tissue sections The hepatic function is not greatly changed by the alterations in the liver The icterus sometimes observed in typhoid is due not to alteration of the hepatic cells but to changes in the cells of the reticulum and to changes in the biliary canals

Mallory and Wreed who made a thorough study of the focal alterations in the liver attributed these changes to thrombosis of the capillaries or to obstruction of the sinuses and compared this process to that which takes place in the glands One can observe in the liver the typical typhoidal granuloma with its great macrophagic activity and central necrosis

In the extrahepatic biliary passages constant lesions are acute cholecystitis chronic ulceration of the gall bladder and calculous cholecystitis It has been demonstrated in some gallstones that the center of the calculi had been formed by bacillary bodies Infection in the biliary canals and in the common duct gives rise to acute inflammation from which almost pure cultures of typhoid bacilli can be obtained by biliary drainage

Bones and Bone Marrow—In the course of the disease or sometimes months or years later periosteal lesions due to the typhoid bacillus occur often with no other manifestations of generalized infection There occur swelling and pain of the long bones (tibia femur) or of the vertebrae with later development of spondylitis A characteristic lesion is the periosteal abscess with intense advanced necrosis Rupture of the abscess causes a lesion of the bone which results in osseous caries extending to the bone marrow with eventual true typhoidal osteomyelitis

Cardiovascular System—In the heart typhoid causes degenerative lesions of the muscular fibers with phenomena of fibrillary fragmentation in the cardiac connective interstitial tissue hemorrhagic phenomena and thrombosis of the vessels are observed (myocarditis)

In the capillaries and veins the thrombotic lesions are due to accumulation of macrophages and precipitation of fibrin eventuating occasionally in complete occlusion Thrombosis independently of cellular obstruction is due to necrosis produced by the action of bacterial toxins upon the endothelium In the course of primary bacteriemia bacteria sometimes accumulate in the capillaries of the papillae of the skin and cause hyperemic reactions with accumulations of macrophages with resulting thrombosis this is typical of dermal lesions during the first week of typhoid (roseola typhosa)

Phlebitis is frequent in typhoid as demonstrated by splenic and pulmonary infarcts at times it may be fatal particularly when pulmonary emboli ensue

Trachea, Bronchi, and Lungs—Typhoid fever causes hemorrhagic tracheitis and bronchitis as well as hemorrhagic pneumonia in which many typhoid bacilli may be found

ted in the direction of the longitudinal axis of the intestine with a predilec on for lymphoid tissue The neighboring tissue of the intestinal wall is always dematous and enlarged sometimes double or triple the normal size Hyper mia of the affected area imparts an intensely red color to the intestine

Slight lesions involve the mucosa and submucosa More intense lesions rovoke different necrotic processes which extend beyond the closed follicles f the intestine to the entire intestinal wall In such cases areas are extremely ltered lymphatic and blood capillaries are blocked resulting in the necrosis f the whole intestinal wall in consequence the intestine perforates often ollowed by localized or general peritonitis

In the colon lesions are most numerous at the cecum and the ileocecal alve sometimes giving rise to pseudotumors which produce constipation or liarrhea Further along the cecum lesions decrease in number since this ortion of the intestine does not have a great quantity of lymphoid tissue Perforating lesions of the colon are very rare The appendix is always in olved and may be the site of extensive ulceration especially in the young ubject

Lymphatic glands of the mesentery are always involved in the typhoid process Beginning with those situated nearest the cecum (the normal area of drainage for the ileocecal segment) the mesenteric lymph glands undergo nflammatory changes showing some swelling and necrosis however not all glands situated in this area of drainage are involved

Rapid necrosis takes place in enlarged glands In those most affected here may be seen a change in appearance caused by hemorrhage and throm bosis Areas of various coloration yellow red gray and black may be ob erved Histologic examination reveals alterations in the structure of the glands The first changes seen are the proliferation of limiting cells of the sinuses and of the reticulum with formation of a large number of macro phages a situation similar to that described in the intestine

Examination of the glands of a patient who has died of typhoid shows that typhoid bacilli are not immediately found in great quantity but the number of bacilli is greatly increased in the glands a few hours after death In this process many macrophages are destroyed but new macrophagic cells replace them The germinal centers apparently disappear being replaced by pale masses of macrophages The gland cells as well as the periglandular tissue are affected proliferation of the reticulum and intense mononucleosis being noted If the glands undergo necrosis and the patient recovers these necrotic areas either cicatrize or are restored by tissue proliferation

Spleen—Splenomegaly is the most constant and characteristic finding in patients dying of typhoid fever This is due to the intense proliferation of the reticulum The same occurs in the mesenteric glands Intense blood regurgi tation of the splenic sinuses occurs The typhoid spleen is of a soft friable consistency intensely red in color with the capsule subject to great tension Sections show the pulp to be of a reddish gray color and containing a great quantity of splenic debris Malpighian corpuscles are easily distinguished sometimes appearing normal sometimes hypertrophic They are gray with

Hemogram.—The blood picture is *typical in typhoid fever in the child* according to observations in this hospital by Barreras. At the end of the first week, approximately the sixth day, the number of leucocytes is between 6,000 and 8,000 per c mm., occasionally from 4,000 to 5,000, with neutrophilia shift to the left, the "stab" count reaching 10 to 20 per cent, lymphopenia and disappearance of the eosinophiles. Before the sixth day the hemogram offers no special information except for an occasional slight leucocytosis and an increased number of "stabs." Leucocytosis (16,000 and higher) is found in the presence of pyogenic infections. The eosinophiles reappear during the final phase of the disease. They are important for the prognosis.

Blood Sedimentation.—Blood sedimentation tests are of value to estimate the intensity of the infection and in convalescence to determine when the child can return to his usual activity.

DIFFERENTIAL DIAGNOSIS

Paratyphoid Fever.—Identification of the bacterium by culture and use of specific sera permit an accurate diagnosis.

Acute Gastroenteritis.—Acute gastroenteritis may mark the beginning of typhoid fever. In gastroenteritis the number of stools is very numerous. The condition begins suddenly—this, however, may also be true of typhoid fever. There is no splenomegaly. Examination of the feces often shows Salmonellae or Shigellae. Blood culture and serologic reactions enable one to make an accurate diagnosis in cases of prolonged intestinal sepsis.

Influenza.—Influenza is characterized by a febrile process which frequently is not accompanied by respiratory manifestations. There is no splenomegaly. The disease has a short period of development. Laboratory examinations in prolonged forms of influenza are helpful.

Pneumonia.—Pneumonia can be confused with typhoid when the pneumonic process is deep and low and physical signs are absent. Cough, however, and changes in the respiratory rhythm, with the absence of abdominal symptoms, are valuable differential data. The hemogram will show an intense leucocytosis. Radiographs will present the characteristic Weil's triangle.

Typhobacillosis of Landouzy.—The clinical picture described by Landouzy almost always corresponds (Cardelle) with a primary tuberculous infection in infancy, especially after the second year of age. Prolonged fever, ballooning of the abdomen, mild splenomegaly, and coma point to a typhoid condition, especially when pulmonary manifestations are absent. An antecedent infection, a positive Mantoux test, and the finding of Mycobacteria, with negative Widal test, permit establishing the diagnosis.

There are no pulmonary signs in the first ten or fifteen days in Landouzy's disease in contrast to the early pulmonary congestion sometimes seen in typhoid fever, so that, paradoxically, pulmonary manifestations may be observed in the beginning of a typhoid fever.

Miliary Tuberculosis.—Miliary tuberculosis sometimes simulates typhoid. Biological tests, radiography, and blood examinations establish the diagnosis.

Genitourinary System—Most typical lesions of the genitourinary tract are focal lesions of the kidney (focal hemorrhagic nephritis)

Muscles—Interstitial hemorrhage is observed with Zenker type degeneration of the muscular fibers Lesions of the rectus abdominis major are very frequent

Brain and Meninges—Meningeal lesions are of two orders one caused by the toxin the other specific in typhoid fever in which McCollum has found the same alterations as in the primary lesions

SYMPTOMATOLOGY

Symptomatology is atypical in the nursling In the older child symptoms are similar to those in adults although milder

In children as in adults typhoid fever may present various clinical forms moderate benign or grave forms

Typhoid fever begins more or less insidiously in the child with a mild progressively rising fever and with few intestinal manifestations At times however and perhaps more frequently than in adults the disease begins with high fever convulsions and headache On one occasion we saw it begin with an acute gastroenteritis and anhydremia which led to a severe acidosis this case developed with extreme gravity and death followed in 80 days

Fever—The temperature reaches 39° or 40° C between the seventh and tenth days maintaining a plateau for 8 to 10 days then descending gradually by lysis in 4 to 6 days then returning to normal Altogether this requires 20 to 25 days so that on the whole the disease has a somewhat shorter and more benign development than in adults The fever generally is of the continuous type with slight morning remission 39° C and evening elevation 39 5° to 40° C progressively rising during the first week and stabilizing in 10 to 15 days A period of wide variations then begins 40° to 37 5° C 39 5° to 36° C etc for 4 to 5 days finally descending to normal or even to subnormal (hypothermic) temperatures for several days Naturally the fever curve may be modified by respiratory complications or complications of some other kind which frequently take place during an attack of typhoid fever

Circulatory Apparatus—Examination of the heart in a typical case does not reveal any changes of importance At times upon auscultation a functional blowing murmur may be heard especially when the temperature is very high Occasionally arrhythmia may be present Blood pressure is maintained within the normal limits if there are no complications

The pulse in infants follows the temperature in general in certain cases there may even be a slight tachycardia A pulse rate of 160 to 180 is not uncommon without the unfavorable prognosis which would be made under similar circumstances in the adult Exceptionally, bradycardia is observed but only in older children A dicrotic pulse is sometimes present but it is much less common than in adults

Respiratory Apparatus—In the majority of cases a mild cough begins on about the fifth or sixth day and auscultation shows rhonchi and sibilant rales proof of a mild bronchitis Occasionally bronchopneumonia occurs as a complication

Complications in the Respiratory Tract

Pulmonary congestion usually develops benignly during the early days of the disease

Bronchopneumonia —Bronchopneumonia is present later in the course of the disease or it may appear during convalescence The process develops with relapses and remissions in two or more weeks The prognosis is serious

Empyema —Empyema is almost always the consequence of a pulmonary complication due to bacteria other than typhoid bacilli

Complications in the Circulatory Apparatus

The most frequent complication is myocarditis which usually appears in the early period

Complications in the Digestive Apparatus

The complication most to be feared in the adult—intestinal perforation—is rarely seen in childhood

Perforation of the gall bladder may also occur in the course of an attack of typhoid fever it is accompanied by peritonitis More than 50 cases in children have been reported

Complications in the Nervous System

Aphasia has already been mentioned There may be other more severe complications meningitis hemiplegia due to cerebral emboli and very rarely polyneuritis We have observed polyneuritis only in patients on a prolonged typhoid diet we believe it is due to lack of vitamin B_1

PROGNOSIS

In children under 2 years of age the mortality is just as high as or higher than in adults after 2 years the mortality decreases and is lowest between the ages of 4 and 10 years When a good state of nutrition has been successfully maintained as with present methods of feeding the prognosis is much better than when patients are placed on needlessly prolonged diets Death at the present time generally occurs from complications myocarditis intestinal perforation encephalitis

*TREATMENT**

It can be clearly stated that despite progress in the diagnosis and prophylaxis of typhoid fever there is as yet no specific treatment for the disease Vaccines sera chemicotherapeutic procedures all remain useless The bacteriophage is too inconstant in its action to be relied upon The fundamental treatment of typhoid fever continues to be hygienic and dietetic

Hygienic and Dietetic Treatment

Bed Rest —Absolute rest in bed is one of the elements of good treatment Good nursing care will always be of great value

*See Chapter 29

Malaria—When a double parasitic cycle exists the fever is continuous and the general state is grave Definitive diagnosis can be established by finding Plasmodia in the blood

Brucellosis—In the child, brucellosis causes a prolonged fever of the undulant type accompanied by splenomegaly and at times by coma Serologic tests and blood cultures enable one to make the diagnosis

Meningitis—Typhoid fever may begin with a meningeal syndrome On the other hand purulent meningitis may begin with coma continuous fever, and splenomegaly Lumbar puncture is helpful

Other Infections—Other septic pictures may be mistaken for typhoid fever Some of these are acute appendicitis acute articular rheumatism osteomyelitis infectious mononucleosis pyelitis and acute endocarditis Close examination of the patient and laboratory tests will aid in making the correct diagnosis

CLINICAL FORMS

Mild Form

These forms common in nurslings are characterized by prolonged pyrexia without great disturbance in the general state At times a slight splenomegaly leads one to suspect *S typhosa* Development of the disease is short ten to twelve days The principal symptoms are absent In the case of every nursling or small child with an indeterminate pyrexia blood cultures should be made as well as the serologic tests for typhoid (Widal Welch and Stuart 1930) The disease does not always develop in a mild form We have seen several nurslings with the classical syndrome of the disease abdominal ballooning splenomegaly intestinal hemorrhage In such cases the prognosis is grave

Severe Forms

Prolonged Form—In some cases typhoid fever may be prolonged for 40 days 2 months or more as in our case of a 3½ year old girl who died after 83 days during which period all the usual complications of the disease were seen

Delirious Form—In this type the child presents nervous excitability with delirium and agitation The temperature is generally high the pulse is rapid It is relatively frequent in children 6 to 12 years of age

Ataxoadynamic Form—This is a form with great prostration which may result in coma There is a tendency toward hypothermia The pulse is weak Carphology is much less frequent in children than in adults

Hemorrhagic Form—In some patients there is a tendency toward hemorrhage sooty gums intestinal hemorrhage epistaxis petechiae

COMPLICATIONS

Typhoid complications are numerous Only those which are frequent can be mentioned in this chapter See Chapter 29

Intestinal Perforation —The only treatment for intestinal perforation is surgical This also applies to perforation of the gall bladder

Specific Treatment

Vaccination —Numerous attempts have been made to treat the disease by vaccine administration either subcutaneously or intravenously but these have not been satisfactory in practice (See also Chapter 29)

Serotherapy —From the first suggestions of Chantemese to the recent work of Schwartzman the proponents of this method have not as yet seen any results proportionate to their enthusiasm (See also Chapter 29)

Bacteriophage Treatment —*We have used bacteriophage treatment in* many cases and on two occasions have seen it bring about the crisis in very severe typhoid fever cases Until more is known about the adjustment of the typhoid bacillus to its bacteriophage this therapeutic measure must remain uncertain

Chemotherapy —Chemotherapy has not given us satisfactory results on the few occasions on which we have used it *

PROPHYLAXIS

The campaign against typhoid is launched by controlling drinking water drainage sewage food handling and carriers

Antityphoid Vaccination —The triple vaccine TAB contains per cubic centimeter 1 000 000 000 typhoid bacilli 750 000 000 paratyphoid A and 750 000 000 paratyphoid B It is given subcutaneously at intervals of 7 to 10 days in the following doses

Up to 2 years	0 2 to 0 4 c c
From 4 to 7 years	0 4 to 0 6 c c
After 7 years the dose is the same as for adults	0 5 1 0 and 1 0 c c

Nurslings less than 6 months of age are unsatisfactory antibody producers and vaccination at this time is usually not satisfactory For intradermal administration of the vaccine in children 3 doses are used 0 05 c c 0 1 c c and 0 1 c c This is the most satisfactory method according to Tuft and others (1941) of all the methods in use because the reaction is reduced to a minimum

SHIGELLOSIS IN CHILDREN

Dysentery is an acute intestinal infection It has been known since the time of Hippocrates †

The disease may occur at any age in the child It is more common during the first year than in the following years It is endemic in all countries especially in tropical regions In general it is more frequent in rural than in

*See Chapters 29 and 65
†See Chapter 29 and Gradwohl (1948)

Feeding—In nurslings breast feeding should be maintained throughout the course of the disease making exceptions according to general manifestations and temperature

If the child is older the necessary quantities of calories and vitamins and volume of liquids should be given taking account of the increased needs of the feverish patient

Adequate diet must be approached gradually dependent upon digestive tolerance A bland diet should be used preferably puree of strained vegetables meat or fish finely minced, eggs, milk, fruit juices or marmalades

A valuable addition to the typhoid diet is glucose and cereals flavored with maltose and vitamins particularly vitamin B_1 (10 mg daily) and vitamin C (100 to 200 mg, up to 500 mg daily) We have not seen serious nutritive alterations (edema typhoid polyneuritis hemorrhagic syndrome) in well fed patients

Blood plasma which brings protective elements as well as proteins and liquid to the patient seems to be indicated in dehydration or in grave forms of the disease The quantity to inject is 20 to 25 c c per kilogram of body weight If the patient is dehydrated liquids shall be administered orally hypodermically or by venoclysis A nursling requires on the average 150 c c of liquid per kilogram of weight daily in cases of severe intoxication more but special care should be taken not to exceed the necessary quantity in order to prevent production of a water balance disturbance

Symptomatic Therapeutics

Diarrhea—When diarrhea occurs give skimmed milk Feeding should be decreased until after the intestinal disturbance improves Antidiarrheal medicaments of the inert type may be used kaolin pectin or a diet of apples for 24 or 48 hours

Constipation—Laxatives of the mechanical type should be used with a base of mineral oil agar agar psyllium etc

Purgative Medication—Purgatives should never be used in typhoid fever

Hyperthermia—We are not particularly partial to antithermics of the chemical type (aspirin amidopyrin) although antithermic medication preferably aspirin may be used The best treatment of typhoid hyperthermia is hydrotherapy

Headaches and Nervous Manifestations—The best treatment is an icecap applied to the head

Myocarditis—Treatment of myocarditis can be summarized as absolute rest ice pack applied to the heart and strychnine Addition of vitamin B to the diet or by injection is useful

Intestinal Hemorrhage—Faced with the possibility of intestinal hemorrhage the following measures should be undertaken immediately

1 Liquid diet for the duration of symptoms
2 Ice bag applied to the abdomen
3 Opium (elixir of paregoric, laudanum etc)

The temperature varies In mild cases there may be slight febriculas or the patient may be apyretic Severe cases present marked hyperthermia with fever of 39° C according to the toxicity, followed by an algid state which may be prolonged for a longer or shorter period and which continues until recovery or death

Associated with bacillary dysentery there may be ocular lesions such as scleroconjunctivitis iritis cyclitis ulcer of the cornea serpiginous ulcer motor paralysis etc Another complication of bacillary dysentery is otitis media This was observed by Nedelson (1939) in 30 6 per cent of 153 patients

PATHOLOGIC ANATOMY

Salas found

Dysenteric bacillary colitis is present in children of a few months of age in the form of follicular ulcerative colitis in children 2 to 12

are changes in the capillaries with dilatation and desquamation of endothelial cells leading to capillary permeability with subsequent infiltration of the mucosa by blood cells

Phagocytosis may be due to metamorphosis of endothelial cells In the more advanced stage of the disease alteration occurs in the Lieberkuhn g l es place in the mucosal cells he submucosa is secondary to action of toxins or bacteria carried through the lymphatic or hematogenic routes

LABORATORY EXAMINATION

Etiologic diagnosis of this disease can be made only by bacteriologic examination of fecal matter Other laboratory findings however, are also important

Microscopic examination of the first feces reveals the presence of leucocytes erythrocytes and cells from the lining of the intestines usually mixed with clots of greenish mucus A few gram negative nonmotile bacilli are present Macroscopically the fecal matter is homogeneous in appearance with bloody spots and striations or a mucohemorrhagic clot At times the material is serosanguineous and often it contains portions of gangrenous mucosa (gangrenous form intensely fetid) Occasionally the material is purulent or mucopurulent having the appearance of pus from sputum or an abscess

In cases of intense dehydration there is lowering of the alkali reserve and acetone is present in the urine Urinalysis reveals moderate albuminuria with granular and hyaline casts erythrocytes and an increase in the number of leucocytes

Data gathered from hematologic studies (G Prado) reveal the following

1 Absence of anemia in 90 per cent of the cases This may be due to anhydremia usually seen in the patients

urban districts and is more prevalent in summer being endemic the rest of the year Outbreaks occur in asylums, nurseries hospitals and other institutions dedicated to child care

Mortality of shigellosis is generally greater during the first month of the child's life Clinical manifestations caused by the Shiga type are more severe than those due to the Flexner group The Shiga type causes the highest per centage of mortality from toxemia at any age in the child

In general, the incubation period of bacillary dysentery is short varying from 24 to 48 hours It may at times be as long as 3 to 6 days

CLINICAL PICTURE

Clinically the disease is divided into the so called acute form and the chronic or prolonged form The acute form includes mild forms or larvate dysentery and hypertoxic nervous algid typhoid gangrenous hemorrhagic and other forms

Aballi gave the following description of the clinical picture of the toxic form

The child apparently in normal health suddenly loses his appetite, and vomits Diarrheal manifestations of a fermentative type follow, becoming phlegmonous and finally mucohemorrhagic and changing from a nonfetid character to a final putrid state The picture is progressively intensified in relation to phenomena of intoxication until the death of the patient sometimes within 12 hours Most cases develop more slowly The intestinal symptoms may be accompanied by abdominal pain and intense tenesmus causing rectal prolapse

At times the vomiting is intense or persistent, aggravating the situation by dehydration The patient s abdomen may be boat shaped (acute development) or distended (rapid form) It is very painful to the touch and to palpation in the region of the ascending colon the cecum and the sigmoid region The pain may be constant causing the child to become restless and to complain continually

In the upper portion of the digestive tract there may be observed swollen gums dry lips and even crusts and bloody fissures—ulceration of cheeks and gums The tongue is moist it may be coated or desquamated

Hepatomegaly is present splenomegaly is absent

As to the respiratory apparatus slight bronchitic phenomena are observed in these cases as well as hyperplastic adenoiditis and tonsillitis.

In the circulatory apparatus there may be noted slow pulse from 80 to 90 maximum to 40 to 60 minimum according to age This 'slow down'' is very marked in severe cases and in the final stages which terminate in rectal prolapse Cardiac tone is weakened There is generally observed no alteration of rhythm and no car liac souffle

Symptomatology of the nervous system is exhaustion and indifference to surroundings in severe cases typhous aspect with hallucinatory phe nomena at times. Cutaneous and tendonous reflexes are diminished

panied by encephalitis The property of producing exotoxins is not constant in the Flexner and Sonne types, and this may perhaps account for the uselessness of the serum in certain clinical conditions due to these organisms

At the Children's Municipal Hospital of Havana, García Montes, Silva, and O Fernandez used the Flexner antidysentery serum successfully in a series of 16 cases They employed 2 or 3 doses of 20 c c in 24 hours, continuing to use it daily until cessation of acute intestinal symptoms and toxemias were obtained

In commenting upon the practical importance of treatment of Shigellosis by sulfonamide drugs we shall discuss the subject according to the findings by Castellaños (1945) Since shigellosis is a disease of the digestive tract, sulfonamide drugs which act on intestinal lesions should offer the best results such as sulfaguanidine and sulfasuxidine These are toxic to a lesser degree and are more readily tolerated and more innocuous than the soluble sulfonamides Some investigators such as Cooper, Zucker, and Wagoner (1941), Halper and Cunningham, Yannet, Leiboitz and Deuth, Tudor, Hardy and Watt (1942), Scroggie Manchaca (1941), Zerbino (1942), etc, have demonstrated that there is no difference in the treatment of bacillary dysentery in the child with one type of sulfonamide or another

Some dysentery bacilli are more resistant to sulfonamides than others According to Hardy and Watt the *sonne* infection is of this type

Although sulfaguanidine and sulfasuxidine are the drugs of choice in shigellosis in cases of diarrhea of unknown etiology where the bacteriologic report might be delayed, it is well to follow the suggestions of certain South American pediatricians (Scrogie, Zerbino, Peluffo, Aleppo, Menchaca etc) to begin treatment of infantile diarrhea with a soluble drug such as sulfathiazole or sulfadiazine Other pediatricians prefer to begin the treatment with sulfaguanidine or sulfasuxidine for 48 to 72 hours If the patient improves he is kept on these drugs without resorting to the soluble forms (sulfathiazole or sulfadiazine)

According to Cooper, in refractory cases of shigellosis, rotation of the sulfonamides at times shows good results Castellaños insists that in Cuba there are many refractory cases of shigellosis which can be overcome by rotation of the sulfonamides, but that sometimes sulfonamide therapy is of no value Such cases according to Castellaños, can be treated by autogenous vaccines (oral and by injection)

Al alli and Castellaños have directed attention in Cuba to the possibility that there may be certain species of Shigella resistant to sulfonamides which have been developed by use of small and continuous doses of the drug

The dosage recommended by Castellaños for the treatment of shigellosis by sulfonamides is

Sulfasuxidine Initial dosage of 0 25 Gm per kilogram of body weight, then 0 25 Gm per kilogram per day, divided into six equal doses In a severe case the initial dose may be omitted and one tablet every four hours should be used day and night

2 Neutrophilia and left nuclear shift present in all cases, myelocytes present in 40 per cent

3 Absence of eosinophilia lymphocytosis and a marked increase in irritation cells

4 Monocytosis as high as 20 per cent, present in a large percentage of cases

5 Nuclear changes (basic chromatin) and alterations of the cytoplasm of the neutrophiles (toxic granules) are always present In serious cases toxic granules may be found in all neutrophiles

6 The bone marrow shows the infectious pattern

Infection is localized in the intestine, and for this reason blood cultures remain constantly negative It is only in very severe cases that these may be positive Only eighteen cases of septicemia due to dysentery bacilli have been reported in medical literature

Diagnosis is usually made by isolating the bacteria from fecal material that is by bacteriologic examination which is the sole means of determining the nature of the disease

Serologic Tests

Macroscopic agglutination methods are used Interpretation of results is difficult since children suffering from dysentery have agglutinins for different types of Shigella Only the following titers or higher titers are of positive value Shiga 1 50 Flexner 1 200 and Sonne 1 150 When a serum shows agglutinins simultaneously for different Shigellae the species which agglutinates at the highest dilution is probably the cause of the infection

TREATMENT

General treatment recommended by Aballi consists in combating the anhydremia and the intoxication by administration of water and electrolytes Opium in the form of a tincture gives good results This may be associated with bismuth and tannin (albumin tannate acetyltannic acid) In prolonged cases autogenous vaccines may be used but although they have proved useful for some investigators others have denied their value

There is no agreement among authorities with respect to the diet for children with dysentery A liquid diet for 12 to 48 hours varying with the toxic state of the patient gives good results Re alimentation should begin with defatted lactic acid milk Patients must be given vigilant care during this period for they may lack tolerance for carbohydrates in which case they must receive an added quantity of proteins This addition may be made advantageously by means of Casec (*Mead Johnson*), or by using the albumin milk of Finkelstein

German authors especially have shown the advantages of treatment of bacillary dysentery with the apple diet (Moro)

Felsen (1939) recommended neutralization of specific toxins by appropriate sera and established the fact that dysenteric serum is of value during the first 24 to 48 hours If no useful results are obtained he recommended using immune blood According to Seidlmayer (1939), the serum is beneficial in cases accom

Sulfaguanidine Initial dosage 0 10 Gm per kilogram of weight, then 0 05 Gm per kilogram of weight Two tablets to be taken as initial dose followed by one tablet every four hours

Sulfadiazine In severe cases the initial dose is from 0 05 Gm to 0 10 Gm per kilogram of weight then 0 20 Gm per kilogram of weight within 24 hours or one may be taken every 4 hours 6 times a day, 2 5 cg per kilogram in each dose Teverett and Nelson recommend half of this dosage

Sulfathiazole In severe cases initial dose is 0 10 Gm per kilogram of weight then treatment to be maintained on the basis of 0 20 Gm per kilogram per day or 0 03 Gm per kilogram of weight in each dose to be taken every 4 hours *

Sulfonamide dosage may be increased or decreased according to the intensity of the clinical picture and depending upon the tolerance of the patient so that a set quantity cannot be maintained

The dosage recommended above is to be maintained while the symptoms are present With improvement in intestinal movements and disappearance of the fever improvement in hydration doses may be taken at 6 hour intervals In severe cases according to Castellaños sulfonamides should be taken for 6 to 8 days even though the clinical condition of the patient is very satisfactory In less severe cases the time may be reduced to 4 days never less

Aballi Jr gives the figures (Table XVIII) of results obtained in the treatment of 74 cases of shigellosis

TABLE XVIII

	CASES	GOOD RESULTS	NO RESULTS	PER CENT OF FAILURES
Sulfaguanidine	54	39	[illegible]	[illegible]
Sulfasuxidine	10	6	4	40
Other sulfonamides	10	6	4	40

PROPHYLAXIS

Contamination by bacillary dysentery is proportional to the conditions of sanitation in the community and to personal hygiene See also Chapter 29

CHAPTER 31

LEPROSY

V. PARDO CASTELLÓ

Leprosy may be defined as a chronic infectious and contagious disease, caused by *Mycobacterium leprae*, presenting periods of quiescence and activity, which preferably affects the skin and peripheral nerves but which may also affect the internal organs of the human body to a greater or lesser extent.

Leprosy is widespread throughout the world. Its prevalence is in inverse proportion to the standard of living of a community. Leprosy is prevalent in backward poverty stricken, filthy centers of human aggregations. However, even among the cleanest, most sanitary, and healthiest peoples, some cases of leprosy are found. China, Indo China, India, Japan, and the South Sea Islands are the greatest leprosy foci. In the Americas, Brazil and Colombia have the largest number of cases, with the Antilles, Mexico, Argentina, and other South American countries following. It is said that there are about 5,000 lepers in Cuba, but only about 2,500 are known to and supervised by the sanitary authorities. In the United States, leprosy is endemic along the coast of the Gulf of Mexico, from Key West to Texas, on the west coast a number of cases are discovered each year, and along the Atlantic seaboard a smaller number is also diagnosed. In New York City there are a number of patients with leprosy at large, since the State of New York has no provision for isolating or otherwise restraining these patients. Most cases in the United States are sent to the National Leprosarium in Carville, La., a model institution, with a total of about 300 patients. In Cuba there are 2 leprosaria, housing about 600 patients, and an official body under the Ministry of Health supporting 10 ambulatory or dispensary centers for the diagnosis of leprosy.

In Europe, leprosy is endemic in certain provinces of Spain and Italy, and a number of cases are found in France, England, and in the Balkans. In Russia and the Near East, leprosy is rather prevalent, especially in Turkey and Asia Minor. Sweden and Norway, which were endemic centers of leprosy during the nineteenth and the early part of the twentieth century, have succeeded in eradicating the disease in the last twenty five years.

Leprosy affects both sexes and all races, but men are more often the victims of this disease than women. The first symptoms are usually seen in early youth, although children and old people may also acquire the disease. One of the earliest cases seen by the author was of a child who had acquired the disease from the midwife and who presented the first symptoms of leprosy at the age of 4 months. In endemic areas, children are considered more susceptible to the infection than adults.

Leprosy is not hereditary nor has a single authenticated case of congenital leprosy ever been reported. Children born of leprous mothers remain

unsatisfactory classification into cutaneous, neural, and mixed types The works of Rabello (1936), Sousa Lima (1938), Schujman (1940), and others in Brazil, and of Baliña and Basombrio (1938), Fernandez (1942), Basombrio (1943), and others in Argentina should be consulted by those interested in the details of these most excellent contributions to the knowledge and understanding of leprosy The author presented a résumé of the subject in 1942 (Pardo Castello, 1943) before the annual meeting of the American Medical Association

The *nodular* or *lepromatous type* shows diffuse infiltration of the dermal and hypodermal tissues It is a granulomatous infiltration composed of numerous large vacuolated badly staining foam cells loaded with hundreds of acid fast bacilli (Virchow s "Leprazellen") and many lymphocytes and plasma cells This type of pathologic change occurs in those tissues that have poor defense and allow an easy and rapid invasion of the specific agent and is therefore typical of the serious and severe forms of leprosy

The *simple inflammatory tissue reaction* is seen in many early cases of leprosy characterized by lymphocytic perivascular periglandular, and perifollicular infiltration vascular dilatation and congestion and edema This type of cellular reaction is seen in recently infected cases where insufficient time has elapsed for proper defense development or for the surrender of the tissues to the invader In time, this type changes into the lepromatous or the tuberculoid type

In the *tuberculoid type* the cellular infiltration is characteristic it occurs in the form of well defined masses situated in the whole of the dermis, usually beginning around the blood vessels, glands and hair follicles, sometimes in the form of cellular nests sausage shaped or oval collections composed of lymphocytes large foam cells, and multinucleated giant cells resembling the infiltrate of the tuberculids or, better, that of sarcoidosis This type is seen in patients whose tissues have adequate defenses against the specific agent as stated in the law of Jadassohn and Lewandowsky (quoted by Sulzberger, 1940) In these tissues it is very difficult to find the Hansen bacillus, which may be seen occasionally embedded in the giant cells never in the large numbers seen in lepromatous tissues Tuberculoid leprosy occurs therefore as a benign type of the disease, with a chronic, usually nonmutilating course at times with spontaneous regression and cure

The simple inflammatory type is usually transitory and in due time changes either to the lepromatous or to the tuberculoid type, but once the type is established it remains so for the duration of the life of the patient except in very exceptional cases still the subject of dispute by leprologists Most leprologists state and the author is in accord with them, that a tuberculoid type never changes into a lepromatous type, but occasionally a lepromatous type may develop adequate defenses and change into the tuberculoid or more benign type This latter occurrence is very rare In any case the presence of lepromatous lesions under the microscope brands the case as definitely "lepromatous" regardless of the simple inflammatory structure of other

healthy and develop normally if removed from their environment Climate and food have no relationship to leprosy This disease is not a tropical condition, although it is common in the tropics it is also frequent in the coldest climates such as Russia as it was in Scandinavia It is a disease which is prevalent among the poorest classes among those who live in crowded quarters and under unsanitary conditions

Leprosy has never been successfully inoculated into lower animals although a similar disease has been described in the rat it is generally conceded that this disease is not the same as that which affects the human being Transmission of leprosy to the hamster has also been reported but so far these experiments have not been corroborated

ETIOLOGY

Leprosy is caused by *Mycobacterium leprae* known as the Hansen bacillus an acid fast organism which up to the present time has remained uncultivated This is a short bacillus with fine ends staining red with Ziehl Neelsen s method and resembling the bacillus of tuberculosis It may be differentiated from the tubercle bacillus because it is usually grouped in masses held together by mucus or at least in cigar like bundles These bacilli are easily found in most cases of leprosy in the mucous membranes of the nose in the lymph which oozes from superficial erosions of the skin or better still in the scrapings of the corium after a superficial cut or after curetting of the epidermis They are usually found in huge numbers in tissue sections of the lepromatous types of leprosy The round or oval masses of bacilli apparently held together by a mucoid substance are called *globi* The bacilli may be found also in the peripheral nerves as well as in the liver and other viscera in advanced cases of leprosy

It is not known whether *Myco leprae* may live outside the human tissues The actual mode of contagion is also obscure although it is assumed in the majority of cases that prolonged personal contact with the patient must exist before the disease is acquired Direct inoculation on the skin with development of an initial lesion has been reported by some observers but it is also generally accepted that the disease may have access to man through the mucous membranes of the nose and mouth

Inoculations of human beings have not been successfully performed although few doubt that it is possible in susceptible individuals

PATHOLOGY AND IMMUNOLOGY

The tissues attacked by *Myco leprae* react in general first in an indeterminate simple inflammatory way and later when the tissues have been in prolonged contact with the specific agent in a nodular or lepromatous type or in a tuberculoid type This has been the basis of the newer classification of the forms of leprosy by the South American school of leprologists We believe the new classification should be universally adopted with elimination of the older

In individuals who have never been in contact with lepers the Mitsuda tes is also positive in the majority of cases

In the early macular type of leprosy corresponding to the simple inflammatory type the observer may predict the future of the patient accordin to the results of the Mitsuda test If the test is negative the patient will develop a lepromatous case with all the severe manifestations of leprosy If however the Mitsuda test is positive it may be safely predicted that the patien will develop a tuberculoid type of leprosy with the usual benign evolution o such type

SYMPTOMATOLOGY

The incubation period of leprosy may be very long in some cases 10 and even 20 years Again it may be rather short a few weeks or a few months In the majority of cases it is impossible to ascertain the infective contact and therefore the time of incubation remains unknown

Leprosy may begin insidiously taking months and even years to develop a few symptoms but it also may start with an acute attack In the first case the phenomena observed are successively as follows rhinitis with profuse mucous discharge or crust formation which makes breathing through the nose difficult epistaxis cutaneous and neural symptoms such as macules nodules disturbances of pigmentation areas of anesthesia and paresthesia especially along the ulnar region of the forearm atrophy of the small muscles of the hands loss of sensation to temperature and pain in the extremities with the development of bullae swelling of the dorsa of the hands loss of hair on the outer half of the eyebrows atrophy of the skin with scaliness reabsorption of the phalanges mal perforans plantaris and other symptoms to be described later

When leprosy begins in the form of an acute attack the patient apparently healthy until a few hours before suddenly develops chills and fever peripheral aches and pains headache arthritis and on the skin a macular or maculonodular eruption with the symptom complex of erythema multiforme or erythema nodosum The diagnosis may be quite difficult and often the case is diagnosed as erythema multiforme of the allergic or infectious (streptococcus) type This acute stage may last for several days or weeks while the patient becomes emaciated Often the condition regresses and a few permanent lesions remain together with beginning atrophy of the muscles of the extremities During this period the erythrocytic sedimentation test may be extremely accelerated as high as 150 millimeters in one hour The number of Hansen bacilli in the skin and in the capillary blood is enormous

When the contacts of a patient with leprosy are examined one often finds one or two such contacts suffering from leprosy of the simple inflammatory or the tuberculoid type quite unknown to the patient These cases show a few macular lesions or one or two infiltrations with few if any bacilli but with the typical disturbances of sensations which characterize these lesions of leprosy Very often only an area of anesthesia is found without apparent discoloration or change in pigmentation

lesions equally the presence of a tuberculoid structure brands the case as "tuberculoid" even if the majority of other skin biopsies demonstrate simple inflammatory reaction

THE LEPROMIN TEST (MITSUDA TEST)

The antigen for the lepromin test is made with tissue rich in *Myco leprae* and is called *lepromin* Although Rost (cited by Jeanselme) as long ago as 1907 made an antigen from a suspension of Hansen's bacilli the application of such antigen to the study of immunity in leprosy was first published by Mitsuda (1924) in 1916 Little attention was paid to his work until the International Congress of Leprologists met in Copenhagen in 1923

The value of the test lies in the fact that an intradermal injection of minute quantities of lepromin antigen produces a definite allergic reaction in certain patients with leprosy while it elicits no reaction at all in others

The test is made by injecting 0 1 to 0 15 c c of lepromin intradermally either into the skin of the scapular region or upon the anterior surface of the thigh above the knee Any other location may be used but Fernández (1942) advises the scapular region because it is usually devoid of hair it is out of the reach of the fingers and is away from the curious eyes of the patient

At the end of 24 to 48 hours there is a light erythema which is attributed to the presence of foreign protein material and which disappears in a few days usually 3 to 4 The site of the test then remains apparently normal until the beginning of the third week when if the test is positive a slight papular infiltration is noted gradually increasing in size until it attains the size of a pea The infiltration is deep in the dermis and the color is bright red There may be some tenderness on pressure and occasionally formation of a central focus of necrosis with ulceration causing a permanent scar

The Mitsuda test is positive in about 90 per cent of normal individuals in practically all cases of tuberculoid leprosy and in about 50 per cent of patients presenting the simple inflammatory type which is characterized by the presence of macular lesions It is negative in practically every case of lepromatous leprosy in about 10 per cent of apparently normal persons and in about 50 per cent of patients with the simple inflammatory type of leprosy

The Mitsuda test is not a diagnostic procedure for leprosy It serves the very useful purpose of determining the defenses of the subject and therefore shows the resistance of the patient to the invasion of the *Myco leprae* *It is therefore a prognostic test* When it is negative the patient shows no defenses and is an easy prey or victim of the disease When it is positive it shows that the subject possesses adequate defenses against the *Myco leprae* and that therefore if he is already affected he will suffer from a mild case and may live without the mutilations and deformities of the severe lepromatous type of leprosy When the Mitsuda test is negative in a person without symptoms of leprosy it shows that the person is susceptible to the disease and therefore should avoid contact with lepers This test is applied to all prospective employees of leprosaria and those with negative Mitsuda tests are not allowed to serve in such institutions

varying in size from that of a millet seed to that of a tomato that is from a few millimeters to several centimeters in diameter The color is deep red dark red or purplish according to location and duration The surface is smooth and shiny in the majority of cases with dilated pilosebaceous follicles sometimes filled with inspissated sebaceous material As a leproma ages the skin becomes wrinkled and scaly resembling senile skin

Lepromas may appear on an apparently healthy skin or on a previously existing macular lesion and may be so numerous as to cover the whole surface of the body but even in the most profuse cases the scalp the flexures the inguinocrural regions and the temporal regions are usually free of lesions The earliest affected parts are the lobes of the ears the eyebrows the fore head the nose the chin and the extensor surface of the extremities especially the elbows and knees Often the lesions are symmetrically situated

Fig 165 —Typical lepromatous facies (Courtesy of Raul Piñeyro)

When they occur on the face the lepromas deform the features of the patient the ears are serrated or grossly lobulated and the lobes of the ear are often studded with deep seated shot like infiltrations When lepromas are numerous on the face the patient presents a cruel and brutish appearance which has been known for a long time under the inappropriate name of *leonine facies*

Lepromas may also present a diffuse appearance in the form of plaques of varying size usually several centimeters in diameter, flat and with in distinct borders At times these plaques are so extensive as to cover large areas of skin They are a variegated color in which deep red pink dark red and purplish mix and intermingle The surface may be smooth wrinkled or scaly according to the time of evolution These are called lep romas "en nappe "

THE CLINICAL FORMS OF LEPROSY

The three fundamental types of leprosy, lepromatous, tuberculoid and simple inflammatory, may affect the skin, the peripheral nervous system and also the eyes, the larynx, the mammary and sexual glands and the viscera. We shall describe in succession the symptoms of leprosy in the skin, in the peripheral nerves and in the other organs mentioned. These histopathologic types correspond to fairly well defined clinical types and may be diagnosed on clinical inspection by the experienced physician. As in many other conditions there are exceptions to this rule and at times even the most experienced diagnostician must wait for a pathologic report before expressing a definite opinion concerning the type of leprosy in a particular case.

The correlation of the clinical *manifestations* of leprosy with the histopathologic changes, the immunologic response and the bacteriologic findings may be better expressed in Table XIX.

TABLE XIX

CLINICAL	PATHOLOGY	IMMUNOLOGY	BACTERIOLOGY
Lepromatous Nodules, lepromas, diffuse infiltration, enlarged lobes, loss of eyebrows, rhinitis, leonine facies, fever and peripheral pains. Mutilations: Nose, extremities	Diffuse infiltration of dermis of foam cells, Leprazellen, with globi. Atrophy of the epidermis. Atrophy of hair follicles and glands. Areas of necrosis	Mitsuda test negative in 90 per cent	Skin: Many bacilli singly, in bundles and globi in sections and capillary blood. Nerves: Numerous bacilli singly and in bundles in and between nerve fibers in sections
Tuberculoid Flat [illegible] tions [illegible] graphi[illegible] [illegible] nerves [illegible] fever [illegible] atrophy of hands. Includes the old neural types	[illegible] no globi. Nerves: [illegible] fuse infiltration, same type	[illegible] test positive in 90 per [illegible]	Skin: Occasional bacilli in sections. Nerves: Occasional bacilli in sections
Simple Inflammatory Macular lesions with little or no elevation, pink, red or leukoderma, areas of anesthesia without clinical changes	Lymphocytic infiltration around blood vessels, glands and hair follicles. No foam or giant cells, no globi	Mitsuda test positive in [illegible] to 40 per cent, negative in [illegible] to 60 per cent	No bacilli or only occasional in sections

The occurrence of simple inflammatory or tuberculoid lesions of the internal organs is questionable since only the lepromatous cases in the advanced periods of the disease show certain visceral changes. It is rather improbable that the early manifestations of leprosy consisting of simple nonspecific inflammation and the benign tuberculoid manifestations of this disease affect the internal organs.

Leprosy of the Skin and Mucous Membranes

The most common and typical lesion is the *leproma*, a circumscribed, elevated, prominent nodule affecting the dermis and subcutaneous tissue and

coalesce and form geographic figures When several lesions of different duration coexist the skin takes on a peculiar variegated appearance

The pigmented macules are frequently an end result of the evolution of erythematous changes but often primarily pigmented macules appear too They are round oval irregular patches of slaty brown or chocolate color and often intermingle with the erythematous and achromic lesions The purely pigmented macules of leprosy affect the trunk and extremities but are much less common than the erythematous

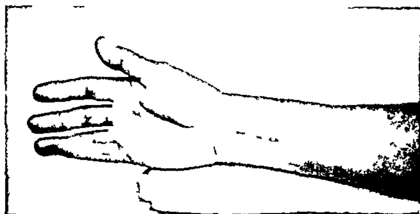

Fig 166—Early simple inflammatory lesion of leprosy A solitary anesthetic erythematous manifestation

Fig 167 Lepromatous manifestations with destruction of the septum of the nose (Courtesy of Raul Piñeyro)

The achromic or leucodermic spots or macules of leprosy often form a halo around the pigmented or the erythematous macules The color is not as white as that of the vitiligo lesions but rather ashy and they are never scaly Often the order is reversed and the achromic spots are surrounded by an erythematous or a pigmented ring *These dyschromic* lesions were known formerly as *vitiligo gravior* and also as *morphea alba gravis*

Lepromas may remain unchanged for a long time several months or years but often they undergo a softening process becoming necrotic and break down to form ulcers with undermined edges dirty purulent floors and foul secretion These ulcers finally heal leaving depigmented or pigmented irregular scars at times atrophic and scaly After attaining a certain size some lepromas begin to recede and finally are reabsorbed without ulceration and disappear leaving depressed scars covered by wrinkled and scaly epidermis The ulcers caused by these lepromas are very slow in healing an easy prey to secondary infection and when situated in the fingers and toes may cause opening of the joints and loss of the phalanges All of these lesions are usually completely painless

The mucous membranes may also be the site of lepromas especially those of the nose Rhinitis is one of the earliest manifestations of leprosy This rhinitis begins in the form of a chronic catarrh with crust formation snuffles continuous secretion of mucus and occasional epistaxis Later the septum of the nose ulcerates the secretion becomes abundant purulent and offensive the nose sinks producing the shape of a saddle or of the so called telescopic deformity that is the lower part of the nose seems embedded in the upper part The mucus contains an enormous amount of Hansen bacilli The palate and the nasopharynx may also be the site of lepromas In the final stage the hard palate breaks down the bone is eliminated in the form of splinters and an opening occurs between the floor of the nose and the mouth water and food escape through this opening The tongue may show chronic glossitis being lobulated fissured and studded with lepromatous nodules Lepromas localized in the larynx are particularly dangerous The voice becomes husky then whispered finally the infiltration of the vocal cords and of the glottis and epiglottis may make intubation imperative if possible or the urgent performance of a tracheotomy

The *simple nonspecific inflammatory* lesions of the early cases of leprosy frequently found in contacts with a certain patient consist of macules of three types erythematous leucodermic and pigmented These lesions usually exist in small numbers at times there are only one or two of them and occasionally they are very numerous

The erythematous macules are the most common and are also observed during acute exacerbations They vary in size from a few millimeters to several centimeters and at times may cover extensive areas of the skin surface usually by the confluence of various smaller lesions The outline is round or oval at times they tend to clear up in the center to form ring like or crescent shapes or they may form circinate or geographic lesions These hyperemic macules are at first smooth but later they may show a furfuraceous type of scales and present a powdery aspect Sometimes these scales are so abundant and imbricated that they resemble the lesions of psoriasis

The color of these erythematous lesions is pink or light red at first but as they grow older they become purplish and at times take a salmon or sepia hue The outlines of the individual lesions are fairly regular and well delineated from the surrounding skin Two or more areas of erythema may

Fig 169—Gynecomastia in a man with lepromatous leprosy (Courtesy of Raul Piñeyro)

Fig 170—Tuberculoid leprosy flat nodules of the skin

Of all these lesions the erythematous are the most common the achromic are rare and the pigmented still rarer

All of these lesions have a common character with disturbances in sensations invariably present in all There is absence of sensation to pain and to temperature but as a rule, the sensation of touch is preserved The touch sensation may be lost in advanced cases

All the macular lesions of leprosy are known by the common term *leprids*

The *tuberculoid* lesions of the skin are usually observed in a pure state but occasionally are combined with the macular lesions described above The diagnosis of this type of leprosy may be difficult but it is possible with the aid of clinical examination by an expert who has seen many cases of leprosy

Fig 168 —Alopecia in a case of lepromatous type of leprosy (Courtesy of Raul Piñeyro)

However the clinical diagnosis should be confirmed by pathologic examinations whenever possible The cutaneous lesions of tuberculoid leprosy are small nodules of the size of a pinhead purplish disseminated or grouped slightly prominent resembling patches of lupus vulgaris or of miliary sarcoid perifollicular papules of lichenoid type resembling the lesions of lichen scrofulosorum dermo-hypodermic nodules the size of a filbert or even larger few in number with a deep red or purplish surface frequently located on the extremities where sometimes they resemble the lesions of erythema induratum of Bazin flat plaques round or oval in outline serpiginous or capriciously outlined covering from several centimeters to large areas of skin especially on the trunk with their centers slightly depressed lighter in color sometimes scaly and the edges well raised covered with papular elevations achromic lenticular lesions or plaques with round oval or irregular outline and with little infiltration in the surrounding skin

These manifestations of tuberculoid leprosy are also anesthetic usually more so in the center than on the periphery

studded with globi and the nerve fibers show progressive degeneration there is not much cellular infiltration or focal inflammation In the tuberculoid types on the contrary the nerves show few if any lepra bacilli but the nerve tissue is greatly invaded by the presence of typical tuberculoid cellular infiltrations composed of lymphocytes epithelioid cells and often giant cells of the Langhans type These cells are grouped in masses resembling the foci as seen in the same type of lesions in the skin A particular type of tuberculoid leprosy of the nerves ends in necrosis causing the formation of a collection of necrotic material with the appearance of pus which adheres to the skin resembling an abscess finally opening and leaving a small ulcer This type of neuritis has been described as *neuritis nodular colliquativa* by Rabello of Rio de Janeiro (1932)

The Trophic Disturbances in Leprosy

The trophic disturbances which are the result of peripheral neuritis described above may be discrete or very numerous according to the individual case They are usually less frequent in early cases and more severe and numerous in advanced cases The tuberculoid types of leprosy may show some of these disturbances rather early in the disease while the lepromatous cases may not present them until the most advanced stage Early manifestations of the lepromatous types are bullae on the bony prominences such as the elbows knees and the knuckles localized gangrenous patches on the hands and feet and painless ulcers usually on the soles especially on the head of the first metatarsal bone or elsewhere on the feet The bullae usually develop suddenly break open or they may dry without breaking and recur repeatedly on the same sites causing extreme atrophy of the skin and even atonic ulcers and finally depigmented atrophic scars The ulcers may also be the result of the breaking down of the lepromas or of localized areas of necrosis and gangrene On the fingers and toes these atonic ulcers foul and bleeding secreting yellowish green pus usually completely painless may open the finger joints and cause mutilation by loss of the phalanges The fingers fall off in pieces without the least pain Secondary infection may cause chronic lymphangitis which is seen along the extremities in the form of dark brown ascending streaks On the feet these mutilations often begin in the form of mal perforans plantaris common in both lepromatous and tuberculoid cases these are located on the head of the first and of the fifth metatarsal bones on the base of the toes or on the calcaneus These are deep ulcers funnel shaped with callous borders reaching deeply into the skeletal parts and destroying them so that sequestra are very frequently expelled through the ulcers without any pain These patients walk with scarcely any difficulty on infected bleeding feet sometimes almost reduced to stumps

As to the skin glands certain disturbances are also observed especially hyperhydrosis The lepra patient perspires freely and soaks his clothes sometimes without exertion especially in the early stages of the disease Later this phenomenon becomes less marked and the sweat secretion may be greatly decreased in the more advanced stages The sebaceous secretion increases

These lesions of tuberculoid leprosy may be difficult to differentiate from those of the simple inflammatory type when the lesions are beginning to change Then the pathologic diagnosis must serve as the deciding factor

Leprosy of the Nerves

Myco leprae attacks the peripheral nerves causing neuritis usually symmetrically The large nerve trunks are either uniformly thickened or present nodular enlargements resembling beads The nerves most frequently affected are the ulnars which may be palpated behind the elbows along the epitrochlear canal the auricular branch of the superficial cervical plexus which may be felt or seen across the sternocleidomastoid muscle the popliteals the peroneals and less frequently the radial and median nerves This polyneuritis may cause intense pain but as a rule the nerve is destroyed and as a result the skin of the affected parts becomes anesthetic The cranial nerves are often affected too especially the facials and the oculomotors

It is generally accepted that this neuritis progresses centripetally at times reaching the spinal roots to cause radiculitis very rarely myelitis has been reported *Myco leprae* seems to invade the skin nerve endings first, the bacilli ascending along the nerve trunks causing their gradual degeneration

Leprous neuritis causes excruciating pains with paroxysmal exacerbations in some patients particularly in the tuberculoid type of the disease which is often confined to the nerves with almost complete absence of cutaneous manifestations Hyperesthesia and burning sensations are also experienced by some patients Later after the nerves have degenerated anesthesia is the persistent phenomenon throughout the life of the patient These zones of anesthesia are usually in the form of bands along the extremities beginning along the ulnar border of the hands and forearms and later spreading to the entire upper extremities Pain and thermal sensations are first affected with the result that the patients suffer burns without noticing them while smoking cooking or leaning against a stove At times the first indication to the patient is the smell of burning flesh The sensation of touch persists unaffected for the longest period and is lost only when the disease reaches its most advanced stages Then the leper cannot pick up a pin or button his clothes without a great deal of difficulty The touch of a feather or of a flake of cotton on the affected parts is not noticed by the patient

This neuritis is also present in all the macular and nodular lesions of leprosy to a greater or lesser degree so that this sign becomes one of the most typical of the disease and serves to identify it in cases when the diagnosis is in doubt

When neuritis is of long standing the complete degeneration of the nerve trunks causes trophic disturbances paralysis muscular atrophies, retractions and deformities of the fingers and toes ulcers and gangrene

Leprous neuritis is an interstitial neuritis in cases of lepromatous leprosy the large nerves being invaded by enormous amounts of lepra bacilli without much defensive reaction The nerves are filled with bundles of bacilli or

placed by scar tissue or may be entirely absent the finger or toe showing a necrotic ulceration instead One of the earliest manifestations observed in the lepromatous type of the disease is the *gable nail of leprosy* described by Pardo Castello (1946) The free edge of the nail is indented and the outer surface of the nail presents a ridge longitudinal to the posterior wall of the nail the whole resembling a gabled roof Diffusion of the lunula over the posterior two thirds of the nail is an early phenomenon in cases of lepromatous leprosy

Fig 17 —Tuberculoid leprosy Enlargement of the auricular branch of the superficial cervical plexus

The muscles are affected early in cases of tuberculoid leprosy and may be equally although not as extensively atrophied in lepromatous cases The first symptoms are present *in the small muscles of the hands* the *interosseous* muscles and the muscles of the thenar and hypothenar regions the hands being thin atrophic the fingers retracted and the palms flat and even Sometimes the line of the heads of the metacarpal bones forms a prominence across and the retracted fingers seem to clench the palm The movements of opposition of the thumb are greatly limited or even entirely abolished The extensor muscles of the forearm are next in frequency to atrophy and as a

first, especially on the face later it undergoes a similar regression and the skin may be dry scaly, and wrinkled in the later stages of the disease The faces of these patients often present a senile appearance due to wrinkling and dryness

An early symptom of lepromatous leprosy is the alopecia of the outer half and later of the whole of the eyebrows The eyelashes may fall off as may the hair of the body especially in the axilla the pubis and the extremities The beard and mustache also become thinned out with finally a complete alopecia of the face The hair of the scalp is not affected in most cases but in others there may be patchy alopecia similar to and often indistinguishable from alopecia areata These patches often affect the edge of the scalp

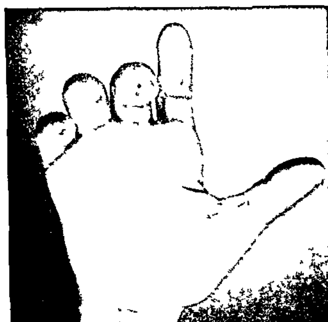

Fig. 11—Tuberculoid leprosy Leper claw Note ulceration of the finger tips and atrophy of the last phalanx

causing the *ophiasic* type of alopecia areata The alopecia of the scalp may be very extensive and the patient may be practically bald It is interesting to note that in the areas along the large blood vessels of the scalp the hairs are preserved the longest Although alopecia in leprosy has been considered as a dystrophic phenomenon it has been demonstrated by many including the author that the hair follicles in these cases of the lepromatous variety are surrounded by cellular infiltration very rich in acid fast bacilli

The nails in leprosy present many and varied dystrophic phenomena They are brittle discolored deformed twisted atrophic sometimes reduced to stumps on the ends of the atrophied fingers or toes The nails may be re

Leprosy of the ovaries and of the testicles is a frequent and an early occurrence in lepromatous patients which explains the sterility of the majority of patients with leprosy When these lesions develop early *in life they may* cause arrest of development these patients may have many of the characteristics of children or of eunuchs Lepromatous orchiepididymitis shows clinically by the presence of small lepromas of the size and shape of lead shot sometimes *larger* causing enlargements of the testicles lasting months or years with final atrophy and fibrosis Finally, the testicles are reduced to small nodules sometimes no bigger than olives These lesions may be among the earliest of leprosy present long before the skin manifestations become apparent in which case the differential diagnosis between the lesions of tuberculosis of the testicles and epididymis and leprosy may have to be considered

Enlargement of the breasts in men occurs rather frequently the mamma *being so prominent, due to the presence of lepromas and sometimes to true* hypertrophy of the glandular tissue that they become feminine in type Patients are very sensitive about this deformity and try to hide it as much as possible The relation of atrophy of the testicles to mammary hypertrophy has been pointed out

Nephritis is a common complication in the advanced periods of lepromatous patients the urine showing casts albumin and renal epithelial cells Hansen bacilli are often found in the urine being quite abundant in advanced cases Amyloid degeneration of the kidneys is a frequent autopsy finding Equally frequent in advanced and terminal cases are gastrointestinal cardiac and pulmonary complications

In lepromatous leprosy there is a bacillary septicemia the *Myco leprae* being easily demonstrated in the capillary blood as well as in the venous blood In tuberculoid forms such findings are never seen

In the great majority of patients with leprosy skin and neural symptoms are mixed in different proportions especially in lepromatous cases but skin and visceral symptoms predominate here with neural and dystrophic manifestations second in importance and frequency On the other hand in tuberculoid cases the skin symptoms are much less varied than in those of the lepromatous types while frequently the neural symptoms predominate visceral symptoms being usually absent The so called "pure neural leprosy" is a type of tuberculoid leprosy of the peripheral nerves with complete or almost complete absence of cutaneous *manifestations except for the atrophic* dystrophic and anesthetic symptoms due to the chronic degenerative neuritis The author has demonstrated that every case of this purely neural type belongs to the category of tuberculoid leprosy, the histologic changes constantly found in the nerves warranting this sweeping statement

In the simple inflammatory nonspecific type of leprosy, the lesions are first of the macular type on the skin and often also coincident with some neural enlargement and areas of anesthesia of the skin These cases are rare and are found only in the very early stages of the disease These are usually cases found when examining the contacts of leprosy cases and often as stated

result the hand effects several atrophic positions such as the so-called "monkey hand," "preacher's hand," and "ulnar claw," according to the degree of retraction of the several fingers and thumbs. Sometimes there are awkward and bizarre combinations of deformities of the hands and feet due to atrophy of the muscles, reabsorption of bone, and mutilations sometimes resembling those seen in chronic rheumatism. In the lower extremities similar deformities may be occasioned by atrophy of the muscles of the feet and calves and of the extensor muscles of the leg. The foot drop, similar to that seen in alcoholic and saturnine polyneuritis, is one of the most common phenomena of leprosy in the lower extremities. In the upper extremities hand drop due to radial paralysis is an infrequent phenomenon. The muscles of the face are paralyzed and later become atrophic due to polyneuritis of the facial and oculomotor nerves. The face becomes expressionless, indifferent, and occasionally there is a paralysis of the orbicularis oris with Bell's syndrome and a progressive atrophy of the muscles innervated by the facial nerve. All these muscular atrophies are more frequent and more extensive in cases of tuberculoid leprosy.

The bones of the extremities may suffer a process of reabsorption without ulceration so that the hands and feet seem shortened and deformed, so much so that the fingers and toes may be reduced to small stumps attached to the metacarpus with the atrophic residue of the nails on their ends. A frequent lesion, especially in the small bones of the fingers, is the so-called *analgesic whitlow* and also *Morvan's disease*. In these cases one or several fingers show inflammation and enlargement, quickly becoming necrotic and gangrenous with the elimination of sequestra, this process being entirely indolent.

VISCERAL LEPROSY

Lesions of leprosy in the viscera are almost exclusively limited to cases of the lepromatous type. Tuberculoid leprosy very rarely affects any of the internal organs.

The most frequently affected organs are the eyes, the anterior segment being the site of inflammation: conjunctivitis, iritis, keratitis, iridocyclitis and glaucoma. Chorioidoretinitis has also been observed. These inflammatory reactions very often end in complete loss of vision.

The lymphatic glands are frequently enlarged, one of the common symptoms of the lepromatous type, especially the glands of the groins and of the axillae. These glands are large, soft, with a certain amount of periadenitis and entirely painless.

Enlargement of the liver and spleen is a common symptom in advanced cases of the lepromatous type and jaundice may be observed in the final stages. The lesions are those of chronic hepatitis and cirrhosis. Autopsy reveals these organs studded with thousands of small lepromas very rich in Hansen bacilli and, in long-standing cases, with predominantly cirrhotic lesions and amyloid degeneration.

Loss of weight lack of the usual normal feeling loss of appetite and sudden increase in the rate of erythrocytic sedimentation are forerunners of a lepra reaction and should be an indication for rest in bed emptying the intestinal canal cessation of treatment with chaulmoogra oil or with Promin and the call to put the patient on a bland diet

LAZARINE LEPROSY

This rare variety of the disease was described first by Zambaco Pasha of Istambul (1897) and later by Pardo Castello and Caballero (1931) of Cuba and by Fernandez Vautrai (1941) of Brazil Leprologists are still undecided as to whether this is a distinct form of leprosy or whether it is simply a variety of the tuberculoid type Some leprologists ignore this type of the disease others consider that it consists only of the prevalence of the formation of bullae and areas of necrosis as a symptom of leprosy However the cases seen by the author and Guillermo Caballero in Matanzas Cuba were to all appearances genuine cases of *monosymptomatic leprosy* consisting of the development of areas of necrosis at the site of an edematous infiltration or of a bloody bulla in a formerly apparently normal person These lesions progress with destruction of the subcutaneous tissue the tendons and muscles and even to the extent of opening of the joints of the extremities causing tremendous mutilations The progress is slow and healing of these necrotic areas leaves retracted and atrophic scars These lesions are always indolent frightful mutilations apparently with no pain whatsoever The diagnosis is made by bacteriologic examination of the necrotic tissues where millions of acid fast bacilli are found with all the characteristics of the *Myco leprae* All attempts to cultivate these bacilli have ended in failure The pathologic anatomy of the affected tissues is that of a tuberculoid infiltration ending in necrosis which is a phenomenon never seen in the usual types of tuberculoid leprosy It is easy to find acid fast bacilli in enormous numbers in the bullae which are the first lesions to appear

The outcome of these cases is occasionally fatal More often the ulcers heal leaving deformities and anesthetic scars and the patient may recover or suffer later from the chronic lesions of leprosy

THE DIFFERENTIAL DIAGNOSIS OF LEPROSY

The diagnosis of leprosy offers no difficulty in the great majority of cases especially the lepromatous type The coincident cutaneous and neural lesions disturbances of sensation and the dystrophic manifestations are characteristic However in some types of leucemia cutis affecting the face the cutaneous nodules and infiltrations "en nappe may simulate the *leonine facies* of leprosy In these cases the absence of anesthesia to pain and temperature as well as the histopathologic changes and the absence of acid fast bacilli will settle the differential diagnosis Mycosis fungoides may offer a similar problem in some cases

above, the patients are unaware of the presence of such lesions It must be emphasized that these patients sooner or later become either lepromatous or tuberculoid cases and this possibility may be predicted by the result of the lepromin test (see p 589)

LEPRA REACTION

Leprosy is a chronic disease lasting many years presenting varied and progressive symptoms over a period of months and years During this chronic course, however, acute episodes may occur these are known as *reactions* or better as *lepra reactions* Occasionally leprosy is initiated with one of these acute attacks the first intimation that the patient has any pathologic condition

This acute condition is characterized, in the lepromatous cases by malaise headache backache chills fever, peripheral painful neuritis, and outbreaks of new nodular lesions bright red in color which may develop in a few hours and which resemble an acute attack of erythema multiforme The fever may be as low as 37.5° C or as high as 41° C with morning remissions and even exacerbations The peripheral neuritis may be accompanied by excruciating pain making sleep impossible The rash composed of erythematous patches papules nodules and urticarial plaques may invade the whole skin surface and the patient seems swollen and deformed beyond belief Old lesions may show central necrosis and ulceration In some patients enlargement of the liver and spleen and acute orchiepididymitis have been observed The patient may die in this acute condition, however that is a rare occurrence As a rule the condition lasts a week or a few months and gradually subsides At times patients remain in acute attacks with very little remission for 6 months to a year

Needless to say, the occurrence of repeated acute attacks aggravates the prognosis in leprosy

During the attacks of lepra reaction the bacilli may be found in huge numbers in the tissues in the peripheral blood in the venous blood and even in the arterial blood Erythrocytic sedimentation rate may be very rapid usually 100 mm or more during the first hour

In tuberculoid leprosy lepra reaction develops in a less dramatic fashion Fever is usually absent and if present is rarely above 38° C There may be activation of the pre existing lesions and a few others may appear Peripheral neuritic pains may be quite troublesome and bacilli may be found in scant numbers in the swollen lesions The patient is usually able to go about and do his chores without much trouble contrary to lepromatous patients in lepra reaction *These must remain in bed unable to move for weeks and months* during which time they may become emaciated and progressively weaker In the acute phase of tuberculoid leprosy the erythrocyte sedimentation rate is seldom much increased usually not more than 20 mm during the first hour

Lepra reaction may be brought about by injudicious treatment with Promin or chaulmoogra oil by intercurrent diseases by excessive eating or drinking by excessive exercise by sexual debauches or at times it may occur without any apparent reason

Loss of weight lack of the usual normal feeling loss of appetite and sudden increase in the rate of erythrocytic sedimentation are forerunners of a lepra reaction and should be an indication for rest in bed emptying the intestinal canal cessation of treatment with chaulmoogra oil or with Promin and the call to put the patient on a bland diet

The outcome of these cases is occasionally fatal More often the ulcers heal leaving deformities and anesthetic scars and the patient may recover or suffer later from the chronic lesions of leprosy

THE DIFFERENTIAL DIAGNOSIS OF LEPROSY

The diagnosis of leprosy offers no difficulty in the great majority of cases especially the lepromatous type The coincident cutaneous and neural lesions disturbances of sensation and the dystrophic manifestations are characteristic However in some types of leucemia cutis affecting the face the cutaneous nodules and infiltrations en nappe may simulate the *leonine facies* of leprosy In these cases the absence of anesthesia to pain and temperature as well as the histopathologic changes and the absence of acid fast bacilli will settle the differential diagnosis Mycosis fungoides may offer a similar problem in some cases

The tuberculoid types of leprosy of the skin and of the nerves may cause difficulties in diagnosis more often than the lepromatous types. Here the cutaneous lesions may be difficult to differentiate from those of sarcoidosis, so much so that some investigators believe that sarcoidosis may be due to *Myco. leprae* in some cases. However, the diagnosis may be made by the histamine test and by the presence of anesthesia in leprosy and its absence in sarcoidosis, but the clinical picture as well as the histopathologic findings may be very similar. *In cases of the pure neural tuberculoid syndrome of leprosy* confusion with syringomyelia is quite possible, but the usual enlargement of the ulnar nerves and the histamine test which remains normal in syringomyelia are sufficient to establish the diagnosis. Alcoholic and diabetic polyneuritis, as well as the polyneuritic syndrome due to avitaminosis, beriberi, lead and bismuth may cause confusion, but they are not difficult to differentiate. In any case biopsy of the ulnar nerve will settle the diagnosis of leprosy.

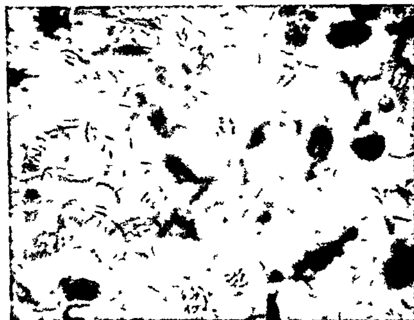

Fig. 178.—Section of lepromatous case. Note the clear spaces (globi) filled with bacilli.

The acute attacks of lepra reaction may be mistaken for acute erythema multiforme, allergic reactions to drugs or food, erythema nodosum of streptococcal nature, and the exanthematic fevers. In countries where leprosy is endemic a diagnosis of acute leprosy must always be in the mind of the general practitioner, and in these cases the presence of Hansen bacilli is usually easy to demonstrate.

It must be emphasized here that the presence of Myco. leprae in the nasal secretions, in the capillary blood, or in dermal scrapings is diagnostic of leprosy.

Fig 1.4 —Section of tuberculoid leprosy of the skin Typical sausage shaped infiltration resembling sarcoid

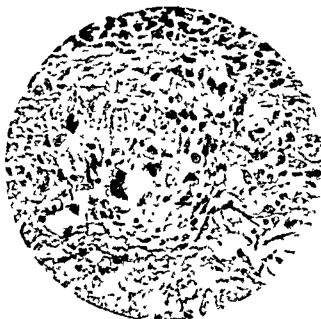

Fig 175 —Section of ulnar nerve showing typical tuberculoid structure in a case of tuberculoid leprosy limited exclusively to the peripheral nerves (formerly called neural leprosy)

The tuberculoid types of leprosy of the skin and of the nerves may cause difficulties in diagnosis more often than the lepromatous types Here the cutaneous lesions may be difficult to differentiate from those of sarcoidosis so much so that some investigators believe that sarcoidosis may be due to *Myco leprae* in some cases However the diagnosis may be made by the histamine test and by the presence of anesthesia in leprosy and its absence in sarcoidosis but the clinical picture as well as the histopathologic findings may be very similar In cases of the pure neural tuberculoid syndrome of leprosy confusion with syringomyelia is quite possible but the usual enlargement of the ulnar nerves and the histamine test which remains normal in syringomyelia are sufficient to establish the diagnosis Alcoholic and diabetic polyneuritis as well as the polyneuritic syndrome due to avitaminosis beriberi lead and bismuth may cause confusion but they are not difficult to differentiate In any case biopsy of the ulnar nerve will settle the diagnosis of leprosy

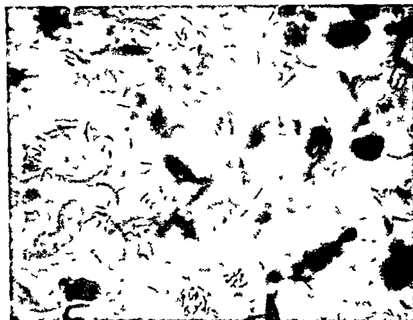

Fig 173 —Section of lepromatous tissue Note the clear spaces (globi) filled with bacilli

The acute attacks of lepra reaction may be mistaken for acute erythema multiforme allergic reactions to drugs or food erythema nodosum of streptococcal nature and the exanthematic fevers In countries where leprosy is endemic a diagnosis of acute leprosy must always be in the mind of the general practitioner and in these cases the presence of Hansen bacilli is usually easy to demonstrate

It must be emphasized here that the presence of *Myco leprae* in the nasal secretions in the capillary blood or in dermal scrapings is diagnostic of leprosy

Similar tests made with salt *solution and with distilled water cause a fleet* reaction similar to the one described above However these reactions are r constant and may be more or less absent or more or less marked according the personal reactivity of the patient due to the individual capacity to libera ' H substance under the trauma of the needle point

This test is adequate for the diagnosis of areas of anesthesia or of ear erythematous lesions due to leprosy especially in children and in noncooperati patients

It must be pointed out however that any type of degenerative peripher neuritis may give an abnormal histamine test and that therefore it is n *exclusively diagnostic of leprosy Furthermore the test is not reliable wh* performed at a room temperature below 24° C or when performed on ag persons with slow or impaired peripheral circulation

It is important in the differential diagnosis between leprosy and syring myelia since in the latter condition the histamine test is normal

The test is read as *normal* or *abnormal,* not as positive or negative

PROGNOSIS OF LEPROSY

The outlook for a patient with leprosy (untreated) is usually unfavorabl Leprosy is a chronic progressive disease especially the lepromatous type The prognosis is therefore grave and only when the cases are recognized an diagnosed early in the disease can one be optimistic as to the future How ever patients with the tuberculoid type of the disease often suffer only fro a few dyschromic or erythematonodular lesions without any discomfort livin a happy and useful life These tuberculoid types have been known to regre and remain asymptomatic for the remainder of their lives which amoun to a spontaneous cure Even in moderately advanced cases of tuberculoi leprosy with enlargement of the ulnar and other nerves and atrophy and r traction of the hands the disease may remain arrested after a number of yea and no further symptoms appear In lepromatous leprosy occasional patient heal after a time usually years the patient presenting no apparent new symp toms but remaining maimed wrinkled senile like with distorted extremitie and *deformed nose* These have been called the 'burned out lepers' and *such cases Myco leprae may be absent*

These remarks refer to cases left without any attempt at treatmen When the patients are properly housed fed and treated the prognosis ma be better and a certain number of cases of leprosy get well although carryin forever the scars of the disease The number of patients paroled from lepro saria as arrested or probably cured is increasing and newer methods o approach to treatment and hygienic measures promise a still greater propor tion of discharges

Most patients of the lepromatous type of leprosy progress toward dis ability blindness laryngitis with occlusive inflammatory lesions leading t tracheotomy cachexia and death Some patients are the victims of inter current disease but it is to be noted that tuberculosis is not frequent amon these patients

but absence of the organism does not exclude the possibility of the existence of this disease It must be remembered that it may be impossible to demonstrate *Myco lep rae* in the macular lesions of the simple inflammatory type and in the tuberculoid lesions of the skin and nerves

The diagnosis of the early macular lesions or of the areas of anesthesia without morphologic skin changes so often found in contacts when following up leprosy patients may offer a serious diagnostic problem and at times the definite diagnosis must be postponed for lack of evidence In these cases the histamine test may be the only method of diagnosis

The Histamine Test

Among the pharmacodynamic tests used for the study of circulatory physiologic and peripheral innervation the histamine test is the most important for the dermatologist It is of very great importance in the diagnosis of leprosy syringomyelia polyneuritis and areas of anesthesia of central and peripheral origin

Technic —

Place a drop of 1 1 000 solution of histamine phosphate on the affected skin to be tested.

Place another drop at a point between the suspected area and the adjacent normal skin and a third drop on the normal skin

Lightly prick the epidermis through these drops using the point of a hypodermic needle being careful not to cause bleeding

Immediately dry the drops of histamine with cotton and carefully watch the sites of the test

Within 25 to 40 seconds after the pricking of the skin the *normal skin* shows an area of erythema with irregular outline usually 5 to 20 mm in diameter later reaching as much as 5 centimeters

In 60 to 100 seconds a wheal forms in the erythematous area centered by the point where the needle entered the epidermis Finally after 3 minutes a hemorrhagic point may appear at the site of the needle prick The wheal usually measures 2 to 5 mm in diameter

The reaction persists for approximately 20 minutes but at times the erythema and the wheal are still present after 45 minutes There are individual variations due to age room temperature and local circulatory conditions The test is useless on the Negro skin

The test on the place *between the affected and the normal skin* shows the same succession of phenomena on the normal half of the skin but on the affected half the erythematous reaction stops abruptly and is absent on that part of the skin but the wheal is always present without the peripheral erythema

On the *anesthetic skin* erythema is wholly lacking while the wheal is present and remains the usual length of time

The test causes no subjective sensations either on the normal or on the affected skin

The test has also been made by scarification and by intradermal injection of histamine but results are more clear cut with the technic described above

at home under sanitary supervision and under the proper treatment There is no more reason to segregate these patients than to segregate early cases of pulmonary tuberculosis when no bacilli are found in the sputum

Leprosy is not a highly contagious disease, and the fear that its presence causes in a community is unjustified It is accepted by all leprologists that contagion of leprosy requires prolonged contact with a patient of the lepromatous type, defective hygienic surroundings, and poor bodily defenses Attendants nurses, employees, doctors, Sisters of Charity and of other religious orders caring for these patients remain healthy and unaffected after years of contact with leprosy patients, and they use only the logical preventive measures that any other bacterial disease requires

The treatment of the disease itself calls, in the first place, for a complete examination of the patient to set aright any deviation from the normal health that may be found, such as intestinal parasites disturbances of gastric or intestinal digestion liver disorders, focal infections, parasitic skin diseases anemia malaria, avitaminosis, and others The patient must be placed in the best possible physical condition to resist the spread of the disease of leprosy The importance of hygienic and nutritional measures cannot be overemphasized here and in this connection leprosy shows as marvelous an improvement as tuberculosis under the proper combination of rest or exercise as the case may be nutritious food high in caloric value and in vitamin content, clean living quarters and plenty of fresh air and sunshine

Milk in plentiful amounts, fresh meat, fish, and poultry, simply cooked and condimented, vegetables, fruits, sugar in plentiful amounts starches in the form of cereals potatoes and other tubers supplemented by calcium salts and vitamins, form the menu of patients with leprosy Eggs may be eaten in moderation, fats in small amounts, but as a rule butter and lard as well as oils should be used sparingly Pork sausages, salted meat, fish, and fried foods are entirely forbidden Chocolate, cakes and pastries are allowed on few occasions, and alcoholic beverages are prohibited Desserts should consist of stewed or preserved fruits, gelatin, hard candies, Junket, and other milk desserts

There is no specific treatment for leprosy Two methods of treatment are used at present with fair percentage of success when treatment is started early in the disease chaulmoogra oil and certain sulfonated drugs, of which Promin is the best known

Chaulmoogra oil is obtained by the expression of seeds of several trees of the *Hydnocarpus*, *Teraktogenos*, *and also in Brazil of the Carpotroche* families The best known species are the *Hydnocarpus wightiana* and the *Teraktogenos kurzii* The expressed oil must be refined neutralized and sterilized before use The ethylic and benzylic esters of chaulmoogra oil have also been used

In the experience of the author and his associates, the best preparation is the refined and neutralized chaulmoogra oil in the form of intradermal and intramuscular injections The ethyl esters are painful and often cause

TREATMENT*

Treatment must be considered first from the point of view of prophylaxis and second from the point of view of treatment of the individual

The most important prophylactic treatment concerns isolation of the patients in sanitaria hospitals or colonies The present tendency among the foremost Brazilian and Argentinian leprologists is to segregate these patients in colonies that is in small communities of about 500 to 1 000 people, with homes stores clubs theaters sports fields and hospitals and dispensaries Here these patients living as they would at home can visit their doctors in the dispensaries to receive advice and treatment as often as needed while performing their work in the community and contributing to their own support These colonies produce their own dairy products truck gardens meat and other products while the inmates help to keep the community clean and orderly being properly remunerated for their work

When a wage earner is committed to one of these colonies his family is cared for by the authorities and properly protected there being for the children institutions called *preventoria* where they are educated and taught a trade until the age of 18 when they are discharged equipped with the necessary instruments or tools for their work

Each institution is equipped with hospital facilities for intercurrent diseases and with beds for chronic disabled patients

One of the most important measures for the prophylaxis and early detection of cases of leprosy is the careful and minute examination of those who have been in contact with a leprosy patient—the near relatives the friends and the neighbors of such patients These contacts frequently have a few undetected symptoms of early leprosy and offer the best opportunity for quick and successful treatment The author has found a number of such cases with one or two isolated lesions where surgical removal of such lesions has been successful and these patients have remained without further symptoms of the disease This fact leads to the belief that leprosy may be locally inoculated into the skin and remain as a localized condition for some time

The treatment of leprosy requires devotion and faith on the part of the physician as well as of the patient The mental attitude of these patients especially when fugitives from sanitary authorities or when finally segregated must be taken into consideration That is why the type of institution recommended and used by the South American leprologists is the most humane and effective of all the patients may live as normal human beings do their work have their homes and in cases where a whole family is affected live as a unit The will to live the hope of getting well and a busy life are important factors contributed by the patient in the treatment of leprosy

It must be stated here that it is not necessary to segregate patients with the simple inflammatory or the tuberculoid type of leprosy unless they cannot live within the set of rules advised by the sanitary authorities or when they are destitute In cases of tuberculoid leprosy or of the early simple inflammatory type with no Hansen bacilli are demonstrable these patients may remain

*See also Chapters 64 and 65

The oral administration of chaulmoogra oil has been abandoned because of the gastric and intestinal disturbances which it causes which prevent the use of therapeutically active doses Intravenous injection of the oil has also been recommended, but it causes acute discomfort, coughing attacks, dyspnea cephalic congestion, tachycardia, and other untoward symptoms It is not advised

Chaulmoogra oil may be used for long periods of time in the manner described above The degree of improvement varies with different subjects It is practically nil in some cases *The steady improvement of others makes* this method of treatment an excellent therapeutic procedure which should be tried in every case In cases of tuberculoid, early simple inflammatory lesions, and early cases of lepromatous types, the success of chaulmoogra oil is at times slightly less than miraculous

It must be stated here that successful treatment with chaulmoogra oil requires a strong and healthy patient, and that the general hygienic measures *already explained the use of calcium, vitamin B complex, and plenty of fresh* air, graduated exercise and rest, proper living habits, and wholesome food are a sine qua non for success Anemic, undernourished patients and patients with intestinal parasites, improper feeding habits, and low defenses do not tolerate chaulmoogra well and their condition becomes aggravated under this treatment

Promin (Parke, Davis & Co), the sodium salt of *p,p'* diamino diphenyl sulfone N N' di(dextrose sodium sulfonate), used originally in the therapeusis of tuberculosis, was used for the first time by Faget and his associates of Carville La in the treatment of leprosy in 1943 (1943 1945) with encouraging results Promin was later considered by Faget and his associates as the best drug ever used in the treatment of leprosy The author and his associates (1946) in 1945 and 1946 used Promin in the treatment of over 30 cases of leprosy with promising results and remarkable improvement in some cases

Promin is furnished in capsules containing 0 20 Gm and 0 40 Gm each for oral use, and in ampules containing 1 Gm of the product in 2 c c of water for intravenous use Promin causes hemolytic anemia and therefore must be used with caution The dosage by mouth varies from 0 20 to 1 20 Gm per diem, and intravenously from 1 to 5 Gm per diem, usually 6 days a week, resting on Sundays The intravenous injections are much better tolerated than the orally administered capsules, and, therefore, at present only the intravenous route is used Treatment is continued for several months with an *occasional* 2 weeks of rest In the author's experience, one patient was able to tolerate a year of continuous treatment with oral Promin, with steady improvement and without any untoward symptoms Anemia is treated with iron salts and good food, but occasionally treatment with Promin must be discontinued due to the low hemoglobin and erythrocyte count Intestinal disturbances, icterus neuritis dermatitis exfoliativa, eczematous reactions and a bluish discoloration of the skin are often observed but *seldom require discontinuation of* the treatment with Promin Lowering the dose, or at the most providing a few weeks rest,

muscular infiltrations and nodular formations The benzylic esters are less irritating to the muscles but offer no special advantage over the pure refined oil

Chaulmoogra oil as received in tin containers from India and Burma is mixed with dead leaves pieces of bark and other detritus and has an acidity of 2 to 3 per cent due to the presence of fatty acids This oil is mixed with petroleum ether in the proportion of approximately 1 part of oil to 15 parts of petroleum ether This solution of the oil is treated with an amount of 38 per cent sodium hydroxide equal to the acidity of the oil The potassium salts of the fatty acids thus formed are separated in the form of soaps To this turbid solution anhydrous sodium sulfate is added the whole filtered and distilled evaporating the residue in vacuum The resulting oil practically neutral in reaction lighter than the original oil is distributed in ampules and sterilized The best chaulmoogra oil deviates polarized light to the right an average of 48°

This oil is injected intramuscularly in doses varying from 1 to 10 c c into the gluteal muscles These injections are at first given once a week later 2 or 3 times a week with a total dosage of 5 to 30 c c weekly As a rule the tolerated dose is about 15 to 20 c c weekly although some exceptional cases may be able to tolerate as much as 30 and 40 c c In most cases 5 c c 3 times a week is well tolerated The dosage must be used according to the weight and the tolerance of the patient Women as a rule are unable to tolerate as high doses as men and in children the dose of 3 c c twice a week is a fair amount In the experience of the author extremely high doses are unnecessary and the maximum of 20 c c weekly for adults is advised It is wise to start treatment with 1 c c twice a week increasing gradually Painful reactions fever increase in the sedimentation rate loss of weight loss of appetite are signs of intolerance in which case treatment with chaulmoogra oil should be stopped and later begun in smaller and slowly advancing doses Continuance of treatment in the presence of the symptoms mentioned above exposes the patient to the danger of an acute lepra reaction After the patient has received 300 c c of the oil it is advisable to allow a rest period of at least 1 month

In early cases and in the macular and tuberculoid lesions the intradermal use of chaulmoogra oil is of great benefit The oil is injected into the dermis of the affected skin in doses of 0 1 to 0 2 c c with a fine needle A certain amount of the oil always flows back along the path of the needle but the wheal caused at the site of the injection insures local absorption of the greater part of the oil dermally injected In this manner the local lesions receive from 1 to 3 c c of the oil and the rest of the dose is injected intramuscularly The advantage of this method of treatment is apparent in the more frequent and quicker resolution of the local lesions which often disappear in a few months leaving only areas of anesthesia which are usually permanent The author strongly recommends the intradermal use of chaulmoogra oil especially in the tuberculoid lesions of leprosy

in cases of chronic painful neuritis, tracheotomy, and amputation of certain fingers and toes when beyond hope of repair

Penicillin and other antibiotics have no effect on leprosy, but they are very useful in the treatment of secondary infections, in the clearing up of chronic ulcers and infections of the eye, ear, nose, and throat

allows the resumption of the optimum amount of Promin by the intravenous route The maximum dose of 5 Gm is not well tolerated and it is better not to go above 3 Gm for women and 4 Gm for men

Promin is not a specific for leprosy It does not seem to act bacteriolytically against *Myco leprae* since, even after prolonged treatment, numerous bacilli are seen in the slowly receding lesions Its therapeutic action is more marked on the lesions of the mucous membranes, and a rapid improvement in the rhinitis, laryngitis, and mouth lesions are usually among the first favorable results The cutaneous lesions improve more slowly and gradually, and some are not affected, while in some cases new lesions appear even while the patient is under treatment with Promin The eye lesions also show remarkable improvement The thickened nerves do not show any improvement under treatment with Promin

Promin is a valuable addition to the treatment of leprosy but must be used with caution, and no definite results can be predicted

Promizole, a later improvement on Promin, has been used recently by physicians of the Carville Leprosarium with favorable results

Treatment of the acute lepra reaction is one of the most important and difficult problems Chaulmoogra oil is entirely contraindicated in these cases, and Promin does not seem to have any action on the symptoms of this unpleasant and serious complication The careful watch on the sedimentation rate, the temperature, and the weight of the patient may warn the attending physician of the impending acute reaction, and by stopping chaulmoogra treatment in time, he may be able to prevent its occurrence *

Patients with acute lepra reaction must be put to bed, a saline purgative administered, and a light bland diet prescribed All previous medical treatments must be stopped Calcium gluconate, hypertonic dextrose solution, and **antimony and potassium tartrate,** 1 per cent solution in 1 to 5 c c doses intravenously, are the best therapeutic measures The intravenous administration of antimonium and potassium tartrate is the treatment of choice, and in some cases it is the only measure that will control the temperature and make the patient comfortable Treatment may be continued for days and weeks without any apparent disturbance except an occasional backache or arthritic pain Very often the lesions of leprosy retrogress under the use of this antimonium salt, the patient regains his normal weight, and the sedimentation rate returns to normal The author has used treatment with this antimonium salt in cases of this sort for months, with very beneficial results for the patient

Other procedures that may be of benefit in certain cases of leprosy are large doses of thiamin chloride, 100 to 200 mg daily, cauterization of ulcerations and lepromas of the mucous membranes with trichloracetic acid, removal of troublesome lepromas, neurotomy, or dissociation of the nerve trunk

*Editor's note (O F) Johansen and Erickson (Proc 4th Internat. Congr Trop Med and Malaria 1948) emphasize that correction of deformities and disfigurement, by plastic surgery are successful in Promin Diasone, and Promizole treated patients.

peruana and Oroya fever were manifestations of the same disease (in Odriozola, 1898) Among other cases, Espinal refers to that of an American engineer who suffered from Oroya fever in Peru, and later, after his return to the United States, had an eruption of verrugas

In 1885, Daniel A Carrion, a medical student, inoculated himself with verruga material After 21 days of incubation, he developed a disease with the typical symptoms of a clinical attack of Oroya fever Carrión himself diagnosed it as such The disease progressed to a fatal end after 18 days of illness According to La Puente, Loli, and Vega pallor of the skin was noted at autopsy, the liver was enlarged, the mesenteric lymph nodes were hypertrophied, almost doubled in size, while the spleen was not as heavy as usual (in Weinman, 1944) It is clear that after an inoculation of verruga material, Carrion developed a typical clinical attack of Oroya fever Hence the conclusion followed that Carrion had demonstrated the etiologic identity of the epidemic disease, Oroya fever with the old known verruga In his memory, the name of "Carrión's disease" was given to the malady

In 1898, Odriozola's monograph "La maladie de Carrion ou la verruga peruvienne" appeared It is an excellent work in which all the data known up to that time were carefully summarized In 1905 Barton discovered the etiologic agent of the disease, *Bartonella bacilliformis* (Strong et al, 1915), in the red blood cells of patients with Oroya fever In 1913 the Harvard Commission, Strong, Tyzzer, Brues Sellards, and Gastiaburu made original and valuable investigations on certain aspects of the disease This commission reached the conclusion that Oroya fever and verruga peruana were two different diseases Although the common opinion of Peruvian scientists was that the two syndromes were of the same origin (based on clinical, epidemiologic, and experimental findings), at that time absolute and complete proof of the etiologic unity was still lacking It was not until 1926 when Noguchi and Battistini published their methods for the cultivation of *B bacilliformis* that it was shown that cultures from verruga and Oroya fever patients contained the same microorganism These microorganisms behaved consistently in the same manner in cultures as when injected into monkeys The identity of the two diseases was proved, beyond any doubt, by these studies The Harvard expedition to Peru in 1937 fully confirmed this theory

Space prevents review in detail of all works performed by Peruvian investigators. The contribution of Peruvian medicine to the knowledge of Carrion's disease is really outstanding

Our knowledge of human bartonellosis has increased substantially in recent years but there are still many important questions unsolved In 1944, Weinman published his excellent monograph *Infectious Anemias Due to Bartonella and Related Red Cell Parasites*, in which not only the actual data on bartonellosis are fully presented and discussed, but the unsolved problems in this field are carefully defined The reader is referred to this monograph for further information

ETIOLOGY

Morphology

The etiologic agent of Carrion's disease, *Bartonella bacilliformis*, presents an extreme *degree of pleomorphism Coccus like, ring, oval, rod shaped (straight, or* more or less curved), and granular forms are found The arrangement of the microorganisms in the red blood cells is also variable Sometimes they form a short chain of cocci or a chain of rods, or they may resemble Chinese letters or a circumflex accent The size of the coccus like forms is 0 3 to 1 micron, and that of the rods 0 5 to 3 microns Curved rods of 7 microns have been seen, but not frequently *B bacilliformis* is gram negative and is stained reddish violet with Romanowsky stains, such as Giemsa Frequently bipolar staining is observed

CHAPTER 32

HUMAN BARTONELLOSIS OR CARRIÓN'S DISEASE

HERNANDO GROOT

DEFINITION

Human bartonellosis or Carrion's disease is a pathologic condition produced by *Bartonella bacilliformis*. It is characterized by a first period in which the pathogenic microorganism may be found in large numbers in the peripheral blood accompanied by a variable degree of anemia and usually pains and fever. The symptoms may be very severe or on the contrary absent and between these extremes cases showing intermediate phases of symptomatology may be found. After this period in most cases a second stage follows in which appears an eruption of small hemangioma like tumors with or without deep nodular elements. The eruptive element has been designated with the name verruga and is known in the medical literature as verruga peruana. The names Oroya fever and less frequently Carrion's fever have been given to the severe forms of the first period in which the final outcome is frequently death. For a better understanding in the present discussion the two periods of the disease will be designated as the noneruptive stage and the eruptive stage respectively.

HISTORICAL REVIEW

It is quite probable that bartonellosis existed in Peru before the discovery of America. Reproduction of the verrugas have been found in statuettes and pottery made by the pre Colombian Indians in Peru who as it is well known possessed a high degree of culture and medical knowledge (d'Harcourt 1939). During the Spanish Conquest in 1531 Pizarro's soldiers were attacked in Coaque Ecuador by a severe unfamiliar disease (Pizarro 1571) which has been considered as bartonellosis. The chronicles of that time designated the disease as Verrugas. Although Maldonado (1931) who has carefully studied historical data thinks that this epidemic was a combination of yaws and malaria it is generally believed that the disease observed in Coaque was bartonellosis. It must be mentioned however that verrugas has not been reported from this region in recent times. The first medical document on the subject by the Peruvian physician Gago de Vadillo was not written until 1630. In the subsequent years there appeared several references to the eruptive stage of the disease among them one of Bueno and later those of Unanue (in Rebagliati 1940) are remarkable. But it was not until the nineteenth and twentieth centuries that really significant knowledge of the malady was gained.

In 1870 a severe disease of obscure origin characterized by fever and anemia attacked the workmen of the Central Railway in the region between Lima and Oroya particularly in the zone between the towns of Chosica and Maturana. It appeared in epidemic form and caused a large number of deaths (approximately 7,000). The Peruvian physicians became greatly interested in the epidemic and the name Oroya fever was given to the disease. Different opinions were held in regard to the origin of such an epidemic. Among them it is important to note was that of Espinal who thought verruga

Motility

In fresh preparations of blood from Oroya fever cases, it is possible to recognize a very slow movement of the Bartonellae within the infected red cells. In young cultures *B. bacilliformis* is motile. Special flagellar stains such as Zettnow reveal three to five unipolar flagella (Geiman, 1944). Using dark field illumination, nonmotile spirals are frequently seen in cultures. These spirals are sometimes quite long, up to 50 microns. They have been considered as abnormal cast off flagella. Such spirals have not been seen in dark field preparations of fresh blood from Oroya fever patients.

Cultivation*

B. bacilliformis does not grow in ordinary media. *Blood agar and Noguchi semisolid* medium for leptospira have been commonly employed. In Noguchi's medium, growth becomes grossly visible near the surface of the medium in about 5 to 15 days. This growth appears often as a nebulous zone 5 to 10 mm. below the surface of the medium. Sometimes, especially in cultures from blood, more or less isolated, granular colonies are observed. It is not rare *that in this medium the growth is poor or, if obtained, is realized with considerable difficulty.*

More recently several media have been developed. Pinkerton and Weinman (1937a) have shown that in tissue cultures *B. bacilliformis* develops within the cytoplasm of cells as well as in the surrounding medium. Jimenez (1940) has used successfully beef infusion agar to which cystine, glucose, and rabbit blood were added. He has also shown that the *x* factor is necessary, but not the *v*, for the growth of Bartonella. Jimenez and Buddingh (1940) have cultivated the organism in the chorioallantoic fluid of the developing chick embryo, 8- and 12-day old embryos were used, and the incubation was performed at 25° to 28° C. Chorioallantoic fluid, aspirated by a pipette and transferred to test tubes, also proved to be successful.

The best results are obtained by using the media devised by Geiman (1941).*

Classification

The general consensus is to classify *Bartonella bacilliformis* as a bacterium. Topley and Wilson (1945) place this microorganism among "miscellaneous bacteria." *We do not* know yet, with certainty, where among the bacteria it should be placed. The genus Bartonella was created in 1913 by Strong et al.

Repeatedly marked resemblances of human Bartonellae to Rickettsiae have been pointed out, and Strong (1942) believes it is wise to separate both from the true bacteria and from the filtrable viruses. *Alzamora* (1945) *believes Bartonella should be placed in an intermediate position between true bacteria and Rickettsiae.*

EPIDEMIOLOGY

Geographic Distribution

The disease is known to occur only in certain regions in western South America. The zone extends from approximately 2 degrees north to 13 degrees south latitude. In Peru, the disease is observed in two regions: one, the Pacific watershed, which includes 21 zones and corresponds to equal numbers of hydrographic formations that extend from the western *slopes of the Andes to the Pacific, the other*, the Marañon watershed formed by the regions around eighteen rivers in the Amazon basin (Rebagliati, 1940). In Ecuador the disease has been found in the provinces of El Oro (Hertig, 1940), and Loja (Montalvan, 1940), near the Peruvian border. In Colombia, bartonellosis occurs in the southwest of the country, in a large area around the city of Pasto (Patiño Camargo, 1939).

*See Chapters 71 and 73.

In the endothelial cells lining blood and lymph channels of viscera from fatal cases of Oroya fever, the organisms are sometimes discrete and rod shaped, but most commonly they appear as granular or amorphous round masses, which distend the cells Sometimes in the edges of these clusters, organisms with more or less typical morphology are seen

In the cutaneous nodules *B bacilliformis* appears within the endothelial cells as rod shaped organisms or as clusters of microorganisms However, the size of such clusters is not as large as that usually observed in the visceral cells from cases of Oroya fever

Fig 176—*Bartonella bacilliformis* in the peripheral blood from a case of Oroya fever Giemsa stain (×1480) (Photograph by C Sanmartin.)

Pinkerton and Weinman (1937) have shown that *B bacilliformis* grown in tissue cultures, appears early as small spherical clusters, 3 to 10 microns in diameter, of sharply stained diplobacillary rods in the cells Later usually by the sixth day the cells are packed with clusters of less discrete organisms, often coccoid, granular, or amorphous in such a way that they give a picture quite similar to that observed in infected endothelial cells from cases of Oroya fever

In other media,* such as Noguchi s leptospira medium or Geiman semisolid or solid medium, the different forms of the Bartonellae are seen, but commonly they appear as clusters of organisms in which it is not easy to recognize the individuality of the parasites except in the periphery Sometimes in these clusters, when Giemsa stain is used, it appears as if the organisms were embedded in an amorphous substance stained a lighter blue The author has observed that in order to study the morphology of the Bartonellae in such cultures it is sometimes advantageous to stain with diluted fuchsin

*See Chapters 71 and 73

of *B bacilliformis* from the intestines of females of *P verrucarum*, which had fed about 60 hours previously (1942) The same author obtained pure cultures of *B bacilliformis* from wild sand flies He has found also that frequently the three species of Peruvian Phlebotomi in the endemic area may present massive infections of the tip of the proboscis with an unnamed organism in certain aspects similar to *B bacilliformis* Such infections have been found in males and in females, and in females which have never had a blood meal

*Phlebotomus belongs to the family Psychodidae of the order Diptera *Phlebotomi* are small, moth like flies, rarely exceeding 5 mm in length Their bodies and wings are densely covered by hairs They may be distinguished easily from other Diptera by the position of the wings which are held upward so that the costal margins form angles of about 60 degrees with each other and with the body (Hertig, 1942) Only the females are hematophagous Their flight is noiseless and oscillating when disturbed During the day they hide on walls in dark corners in dark rooms, caves, crevices, etc The breeding places are difficult to find These are moist, dark places, with organic matter, under stone, in rock interstices in cracks of old walls, in chicken houses In the endemic areas in Colombia, Phlebotomi are found in enormous numbers in the humid and dark caves where Panama hat weavers work

Hertig states that *P verrucarum* readily bites man, enters houses freely, and is found associated with man and domestic animals, both in buildings and in outdoor places far from human dwellings *P peruensis*, similar in habits is scarce when compared with *P verrucarum* *P peruensis* is usually found in the upper limit of the verruga zone *P noguchii* appears to have an entirely outdoor existence, and does not bite man This sand fly commonly feeds on field mice

Probably in Colombia as in Peru, the insect vector is a Phlebotomus Several species of Phlebotomi have been found in the Colombian endemic areas but not those usually found in Peru The recorded Colombian species are *P longipalpis*, *P evansi*, *P osornoi*, *P colombianus*, and *P monticolus* var *incarum* (Ristorcelli and Dao, 1941)

Sources of Infection

The only known reservoir of virus in human bartonellosis is man Man and the insect vector are the only living beings known to be naturally infected with *B bacilliformis* Man may have the microorganism in the peripheral blood long before the appearance of symptoms during the different manifestations of the disease, and for a long time after the clinical attack The existence of asymptomatic human infections in people living in endemic zones, either with or without previous history of the disease, has been demonstrated several times (Battistini, 1927, Mackehenie 1934, Weinman and Pinkerton, 1937, Howe, 1943a, Groot, 1946) The incidence of such carriers in the infected areas is significantly high—10 per cent—perhaps higher Thus, from the present data, the importance of man as a source of infection appears to be clear

In these three countries the disease is observed in the same system of mountains, the Andes, in regions with similar definite conditions of topography, hydrology, climate, fauna, and flora These zones are found in the narrow valleys formed by rivers and streams between mountains, and in the highly inclined slopes of these, near the water courses The climate is relatively hot in the day and cool during the night In Peru the vegetation is rather luxuriant down in the valleys, but scanty in the surrounding mountains The zone is sparsely inhabited In that country the disease is endemic at altitudes between 500 and 3,000 meters (1 640 and 9 840 feet) above sea level The lowest verruga zone recorded by Rebaglati (1940) is Esquina de Asia, at 200 meters (656 feet), but it is not stated that these cases were not imported (Weinman, 1944) The highest zone, according to the same author, is Huasta, at 3,375 meters (11,700 feet) In Colombia, according to the present available information, bartonellosis exists only at places with altitudes between 1,300 and 1,850 meters (4,260 and 6,000 feet), with daily temperatures of 18° to 25° C (64° to 77° F), somewhat lower during the night, and with the same conditions as previously stated, except that these regions are densely populated and that the soil is very fertile and the vegetation abundant in the slopes of the mountains as well as in the valley bottoms In Colombia the upper and lower limits of the zone are sharply defined In many places in which the density of houses and population is the same above and below 1,850 meters (6,000 feet), all persons who live above such altitude have nevertheless remained free from the disease

Transmission

In 1913 Townsend reached the conclusion, a priori that the insect vector was a sand fly, a Phlebotomus So certain did he feel of his inference, that he called the sand fly *Phlebotomus verrucarum* (Noguchi, Shannon, Tilden, and Tyler, 1928) Subsequent studies have confirmed his point of view Noguchi et al (1929) injected saline suspensions of crushed wild Phlebotomi, captured in the verruga zone, intradermally into rhesus monkeys, and in this way obtaine an infection in these animals The infection was detectable only by blood cu tures, which yielded positive cultures for *B bacilliformis* Similar results we obtained by Battistini (1929, 1931) Wild Phlebotomi collected in the endem area have given pure cultures of *B bacilliformis*, and, when fed on the monkeys, produced infections detectable by blood culture (Battistini 19 Hertig 1942) The sand flies selected for Hertig s experiments were *P v rucarum*

From the Peruvian verruga zone three species of Phlebotomi have bee scribed *P verrucarum* (Townsend, 1913) *P peruensis* (Shannon, 1929) *P noguchii* (Shannon 1929) Noguchi Shannon and associates thought the role as vector of *P noguchii* was certain that *P verrucarum* was a pro transmitting agent, and that the role of *P peruensis* was doubtful (Hertig (1942) however, believes that the females of Shannon s s material were predominantly *P verrucarum* Hertig with his exper and observations has demonstrated at least in the regions studied by hi the most important vector is *P verrucarum*

The degree of infection in Phlebotomi in natural conditions is a not yet answered It may probably vary from one place to another

The mechanism of transmission is through feeding In regard to of Bartonella in Phlebotomus, Hertig has been able to recover pure

in 1 case The same author states that in five patients who had not previously lived in "verruga" zones, the disease appeared after 19 to 30 days of residence in the infected area

For a better understanding, *it is desirable to describe separately the* two periods of the disease the noneruptive stage and the eruptive stage Within the first, the syndrome usually known as Oroya fever will be discussed

Noneruptive Stage

The clinical manifestations in the noneruptive stage vary from very severe cases in which high mortality is observed to cases in which symptoms are either absent or are very slight and can easily pass unrecognized In the latter, the so called noneruptive stage really does not exist (from the clinical standpoint), and thus the appearance of verrugas is the first observed symptom All intermediate cases may be found The severe case will be described first

OROYA FEVER

The onset may be acute with high fever reaching 40° C (104° F), chills and sweating, but more commonly, it is insidious, marked by malaise, headache, pains in the joints and long bones, and fever *A rapid,* progressive anemia develops from the beginning

As the disease progresses, the fever continues, and the anemia is more and more marked The skin and mucous membranes become pale The number *of red blood cells diminishes to less than two million per cubic millimeter,* sometimes to less than one million, and large numbers of Bartonellae are found in the erythrocytes The pains are severe The general state of the patient is poor The tongue is coated at the center, red at the point and edges There is anorexia, sometimes polydipsia nausea, vomiting, and *frequently diarrhea* Epistaxis and presence of petechiae in the skin are also frequent The arterial tension is low and the pulse is always accelerated, both in febrile and in apyretic periods Cardiac murmurs are often heard There is intense polypnea Commonly prostration is observed and the patient, *indifferent* to his surroundings may present delirium On the contrary, insomnia may occur The lymph nodes are enlarged The liver is commonly, but not always moderately hypertrophied In most cases the spleen is normal in size Complications such as paratyphoid infections have been reported

In fatal cases all symptoms are aggravated, the prostration increases insomnia is frequent, sometimes delirium occurs, the number of Bartonellae in the red cells is greater, anemia becomes more and more severe, diarrhea is always observed complications may appear—frequently pericarditis or a secondary infection—and the patient dies

The duration of these fatal cases is variable There are extremely acute cases in which death comes as early as the tenth day, but usually the fatal outcome is not observed until the third to the sixth week

In Jaramillo's series, death took place from the twenty first to the twenty sixth day in 4 cases, and at the fortieth day in 1 case (1939) In Groot's

Epidemics and Endemicity

In infected areas Carrion's disease remains endemic most of the time However, under certain circumstances the disease extends to neighboring zones especially after the rainy seasons It seems that most of the cases among natives, in endemic areas occur early in childhood and the incidence in adults is low However a large number of asymptomatic infections is observed It is significant to record that when people from a disease free region move to an endemic area—at least in Peru—they become infected sooner or later provided they remain unprotected from the bites of Phlebotomi Carrion's disease usually evolves in its most severe forms in these previously unexposed persons

Epidemics may occur when large numbers of previously unexposed people move into the endemic areas or when the disease extends to or appears in new territories Example of the former is the well known epidemic of 1870 in the Central Railway workers (see above) Recently in Colombia a very serious epidemic of Carrion s disease developed in zones where the disease had not been reported before (Patiño Camargo 1939) The epidemic began in 1936 reached its peak during 1938 1939 and 1940 and from 1941 began to subside slowly Up to September 1941 the infected area included the valleys and neighboring zones of the rivers Guáitara Juanambu Pacual and Mayo By the end of 1941 cases began to appear in Bolivar a somewhat isolated village about thirty miles north of the endemic zone and separated from this by a high (2 200 meters—7,200 feet—of altitude) chain of mountains This village because of such proximity had been permanently and carefully watched from the epidemiologic standpoint during the previous years No cases had been reported, but the presence of large numbers of Phlebotomi (species not identified) had been fully established The appearance of the disease in Bolivar apparently occurred after patients in the eruptive stage went to reside there

Under epidemic conditions there is no difference either in sex or age incidence The case fatality rate seems to be somewhat higher during epidemics than in endemic conditions

SYMPTOMATOLOGY

Incubation Period

The incubation period varies considerably In experimental human cases it has been from 16 to 21 days In the present discussion the end of the period of incubation is considered as the moment when the first clinical manifestations are observed and not from the presence of Bartonellae in the blood The author (1946) reported the case of a patient who developed Oroya fever 4 months after she had positive blood cultures for *B bacilliformis* The patient had been living in the endemic area for the last 3 years

Ricketts (1947) found in 7 cases which remained in endemic zones from only a few hours to 3 days the following incubation periods from 20 to 23 days in 4 cases 40 days in 1 case from 88 to 90 days in 1 case and 100 days

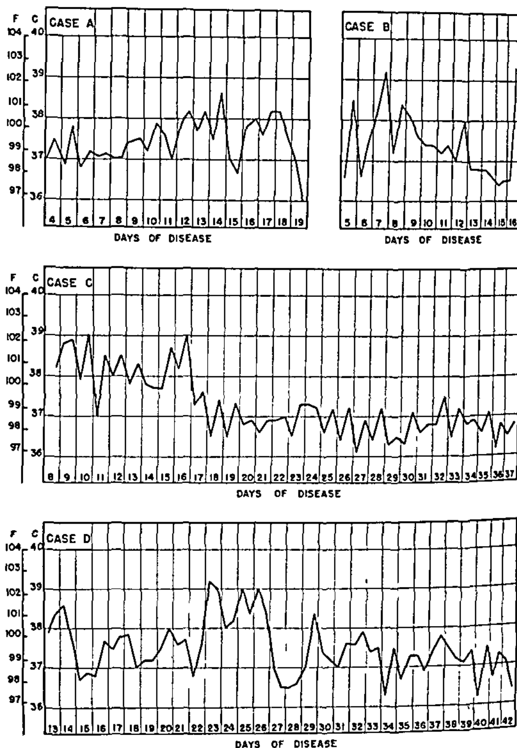

Fig 177 —Temperature charts of 4 patients with Oroya fever Patients *A* and *B* died Patients *C* and *D* recovered.

observations, death came from the fifteenth to the eighteenth day in 4 cases from the nineteenth day to the twenty second day in 4 cases, from the twenty seventh day to the thirtieth day in 2 cases and from the thirty eighth day to the forty sixth day in 4 cases

In cases which recover, after a variable period of 2 to 6 weeks, the fever decreases slowly, the Bartonellae disappear from the blood stream (as detected by films), sometimes quite suddenly There is an amelioration of all symptoms, pains decrease, the anemia ceases, and the number of erythrocytes begin to increase slowly The patient enters convalescence In certain cases the disappearance of the Bartonellae from the blood stream does not coincide with the cessation of the anemia (Hurtado et al, 1938) but it usually does

The rate of decrease in the percentage of infected red cells in most cases follows a similar trend

In favorable cases, infected erythrocytes are detectable by films for a period of time This finding varies in different patients in 3 cases reported by Jaramillo Bartonellae disappeared at the twenty seventh, twenty eighth, and thirty eighth day respectively, after the beginning of the disease, and in 5 cases studied by the author the disappearance occurred at the thirteenth, twenty third twenty fourth, twenty eighth, and forty eighth day, respectively

The end of Oroya fever is considered when the Bartonellae are no longer seen in the films, fever has disappeared, anemia is no longer being produced, and the number of erythrocytes has begun to increase

In most cases, and very often, when the patient has not recovered completely—1 to 2 months after the termination of the Oroya fever—the eruption of "verrugas" appears Apparently only in few cases does eruption not occur

Some Symptoms in Detail —

Fever —The fever follows no definite pattern and extreme variations are observed Generally it is of the intermittent or remittent type or a combination of both There is almost always a slight or marked evening exacerbation The difference between the morning and evening temperatures is usually not more than 1 5° C (2 7° F), but this may at times be 2° C (3 6° F) The remittent type seems to be more common In favorable cases, fever decreases slowly (in lysis) In fatal cases, death may come with high, normal or subnormal temperature The temperature rarely exceeds 40° C (104° F) Of 21 cases studied by the author, in only 3 were there exacerbations above 40° C In Jaramillo's series, out of 10 cases, only 1 showed more than 40° C The highest temperature is commonly between 38° an 39 5° C (100 4° and 103 1° F) The morning temperature may be normal, and usually is not above 38° C (100 4° F)

The Blood —From the beginning of the disease a rapid, progressive anemia develops Figures of about 1 000 000 red cells per cubic millimeter

are common The rate of decrease in the number of erythrocytes is quite rapid Sometimes as many as 300 000 red cells per cubic millimeter of blood are lost in twenty four hours *The volume, diameter, and thickness of the* red cells are greater than normal The mean hemoglobin concentration is usually low (Hurtado, Pons, and Merino, 1938), but it may be normal (Groot 1941) The blood volume is decreased especially when the anemia is very pronounced Hyperbilirubinemia is often observed but by no means is it constant The regenerative activity of the bone marrow is well marked and large numbers of reticulocytes and normoblasts are found in the peripheral blood *The number of these cells usually is proportional to the seriousness* of the anemia Quite often megaloblasts are found

The number of Bartonellae in the red cells varies Sometimes 99 per cent of the erythrocytes are infected, and it is possible to find ten to fifteen organisms in a single cell, but these are extreme cases Basophilic red cells and macrocytes are usually less infected Reticulocytes uncommonly present Bartonellae unless the number of microorganisms in the peripheral blood is very high Only in exceptional cases with a very high degree of parasitism are the microorganisms found in the normoblasts Bartonellae are seen some times in the cytoplasm of monocytes

Apparently destruction of the red cells is the fundamental cause of the anemia The mechanism of such destruction, however, remains completely obscure Production of hemolysins by the Bartonellae has never been demon strated in vitro or in vivo Direct action of the Bartonellae on the red cell and exaggerated erythrophagocytosis have been considered as possible, but definite proof is lacking

Leucopenia may be observed at the beginning of the disease It is *generally accepted that in uncomplicated cases* the number of leucocytes is customarily normal (Hurtado, 1938) In 19 cases in which blood counts were performed almost daily during the course of the disease, the author has ob served in 13 cases normal counts throughout the entire course of the disease in 3 cases, normal values throughout the course of the disease *with slight* leucocytosis during convalescence, and in 3 cases, occasional slight leuco cytosis, with normal values most of the time

The differential count is not typical It is possible to find either a very slight lymphocytosis or, more commonly, polymorphonucleosis

During the period of severe anemia, there is always an increase in young polymorphonuclears and younger cells of the myeloid series

The sedimentation rate is markedly increased, giving values between 100 and 172 mm in 1 hour with the Westergren method Making the correction for the degree of anemia, values from 85 to 120 mm in 1 hour are usually *found The Gaté Papacostas formol* gel test is sometimes positive as well as the flocculation of serum globulin with distilled water (Groot, Mayoral, and Martinez, 1941)

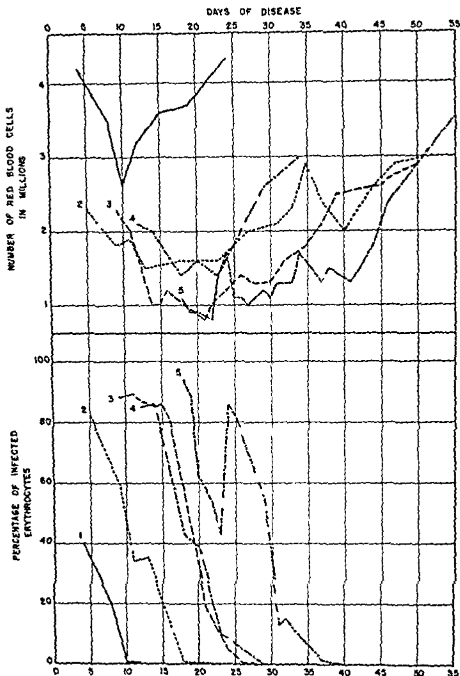

Fig 179.—Red blood cell counts made at frequent intervals with associated percentages of infected cells in 5 untreated recovered cases of Oroya fever

mal Weiss (1932) has described cases in which the appearance of verrugas took place 18 months later and frequently periods of 6 to 10 months have been recorded In (2), conditions similar to those of (1) occur In (3) the constitutional symptoms may precede the eruption for *only a few days and these symptoms* may be exacerbated at the beginning of the eruption to recede completely shortly thereafter The incidence of (4) seems to be not rare Such an occurrence was observed by the author in 9 out of 42 verruga cases in epidemic conditions

Fig 179 —Human bartonellosis eruptive stage Disseminated miliary and nodular lesions of the face Palpebral conjunctiva of the right eye with verrugas Most of the lesions were pink or bright red The patient still shows emaciation due to the preceding attack of Oroya fever

In the eruptive stage the lesions may develop from (1) the superficial layers of the skin and certain mucosae (2) the deep layers of the skin and (3) the subcutaneous tissue Verrugas in (1) usually small are designated as *miliary , verrugas in (2) and (3) as nodular Miliary lesions are* small 1 to 3 mm in diameter or somewhat larger 7 to 8 mm They are round raised hemispheric red or cherry colored covered with a thin layer of shiny skin sharply circumscribed from the surrounding tissue which presents no sign of inflammation Early in their evolution verrugas which grow in the deeper layers of the skin give upon palpation the sensation of a hard nodule later they appear at the surface of the skin The lesions which develop in the subcutaneous tissue at first appear as hard nodules which may reach a size of several

The occurrence of autoagglutinins seems to be rare Monge described some cases and the author had the opportunity of finding 1 case in a series of 26 patients

Pain—Pain is always present and may be the first observed symptom Often it persists during the convalescence The pains are located most commonly in the joints—hands feet knees ankles—and in the epiphyses of the long bones Pressure on the bones may be painful or may exaggerate an already existing pain These pains may be intermittent Rachialgia is frequently observed Headache is quite common and is almost always constant

Nervous Symptoms—Among the most common symptoms usually reported are dizziness and vertigo Insomnia is frequent Delirium often occurs especially just before death and in such cases carphologic movements may be observed Convulsions have been reported but it seems that they are not usual

Urine—The urine is usually concentrated and dark amber in color It may contain small amounts of albumin usually not more than 0 20 Gm per liter and some hyaline and granular casts Urobilinogen is commonly increased

MILD CASES

Numerous cases show only a mild symptomatology for a few days to weeks or even a month or more of duration characterized principally by slight and occasional fever malaise arthralgias, often moderate anemia In these cases small numbers of Bartonellae may be seen in blood films or the microorganism may be demonstrated only by blood cultures Ordinarily these patients do not need to interrupt their usual occupations or remain in bed The eruption of verrugas may take place when such constitutional symptoms are still present When this is the case the fever usually mounts and the joint and bone pains are markedly increased In other cases this vague symptomatology subsides and after a variable period of time the eruption appears

On the other hand the clinical manifestations may be absent or so mild that they pass unrecognized

Eruptive Stage

The eruptive stage is characterized clinically by the appearance of small hemangioma like tumors in the skin and subcutaneous nodules In most cases constitutional symptoms of variable intensity such as fever and arthralgias are present at the beginning of the eruption

Verrugas may appear (1) after a previous attack of Oroya fever (2) when the patient has presented some time before mild symptoms of the non eruptive stage of the disease (3) when the patient has been presenting mild constitutional symptoms in the days or weeks immediately prior and still presents them and (4) when the patient gives no history of previous disease is apparently in good health and cannot recall any particular symptom in the preceding days or months In (1) verrugas usually appear from 2 to 8 weeks after the remission of the anemia when the patient is still convalescing from the previous attack of Oroya fever and the number of red blood cells is not yet nor

centimeters The nodule adheres to and raises the covering integument and at this point may regress without causing further pathologic changes, except sometimes the reddening of the skin, or, on the other hand they may erode the skin, reach the surface, and appear then as red tumors with irregular contours frequently pediculated Such tumors are usually designated as verruga of the "mulaire" type

Miliary lesions may appear anywhere in the skin or in the mucous membranes of the mouth, nose, and eye, although they are more frequent in the face and limbs They may be few in number, or, on the other hand, extremely numerous disseminated throughout the surface of the body Benavides (1942) reported a case with 1,272 eruptive elements

Fig 189—Human bartonellosis eruptive stage Large verruga of the mulaire type

Nodular and tumor lesions ("mulaire") are far less numerous than miliary verrugas Subcutaneous nodules often appear near the elbows and the knees where they are usually painful and may cause functional disturbance of the limbs

Verrugas bleed easily, and some of them may appear to be covered by a blood crust "Mulaire" lesions are especially prone to bleed and are almost always secondarily infected

The duration of the eruption varies It may persist from 1 month to 2 years (Odriozola, 1898), but usually it lasts 1 to 6 months In Jaramillo's series

Fig 180.—Human bartonellosis, eruptive stage. Two verrugas of the ear

Fig 181.—Human bartonellosis, eruptive stage. Large verruga of the left cheek.

centimeters The nodule adheres to and raises the covering integument and at this point may regress without causing further pathologic changes, except sometimes the reddening of the skin, or, on the other hand, they may erode the skin, reach the surface, and appear then as red tumors with irregular contours frequently pediculated Such tumors are usually designated as verruga of the "mulaire" type

Miliary lesions may appear anywhere in the skin or in the mucous membranes of the mouth, nose, and eye, although they are more frequent in the face and limbs They may be few in number, or, on the other hand, extremely numerous, disseminated throughout the surface of the body Benavides (1942) reported a case with 1,272 eruptive elements

Fig. 182—Human bartonellosis eruptive stage Large verruga of the mulaire type

Nodular and tumor lesions ("mulaire") are far less numerous than miliary verrugas Subcutaneous nodules often appear near the elbows and the knees where they are usually painful and may cause functional disturbance of the limbs

Verrugas bleed easily, and some of them may appear to be covered by a blood crust "Mulaire" lesions are especially prone to bleed and are almost always secondarily infected

The duration of the eruption varies It may persist from 1 month to 2 years (Odriozola, 1898), but usually it lasts 1 to 6 months In Jaramillo's series

the duration of the eruptive stage was 7 weeks in 2 cases 8 weeks in 1 case, 9 weeks in 1 case 12 weeks in 2 cases and 20 weeks in 1 case (1939)

Frequently the eruptive elements appear in successive outbreaks so that it is possible to find in the patient verrugas in different phases of evolution The lesions heal without leaving a scar unless they have been secondarily infected

The preceding description does not cover all the observable clinical cases but it certainly applies to the large majority Odriozola described some cases in which Oroya fever followed the eruptive stage Likewise forms with mild symptomatology and marked rheumatoid pains which persist for months or years and which cease with the eruption of verrugas have been reported as well as cases of long duration in which the principal symptom was the repeated appearance of discrete eruptive lesions

IMMUNITY

People who have had the disease and continue to live in endemic areas in most cases do not present second attacks of Carrión's disease Certainly some cases of repeated attacks of verruga have been reported but they are far from common This leads us to think that in most cases a lasting immunity develops after the disease From experimental data we know also that monkeys show resistance to reinoculations

The numerous cases in which Bartonellae are found in the blood long after recovery from the disease indicate that the immunity which usually follows the clinical attack coexists at least in some cases with latent infection and the presence of Bartonellae in healthy people without previous history of the disease shows that in these cases there is a balance between the infected man who cannot eradicate his infection and the infective agent which does not cause apparent disturbances in its host This balance may be disturbed with the consequent development of Carrión's disease in the carrier or possibly it may not be disturbed but the infection may remain completely asymptomatic throughout its course This condition is similar to the state of premunition which exists in animal bartonellosis In rats infected with *Haemobartonella muris* the infection usually remains asymptomatic but when such rats are splenectomized the latent infection is changed into apparent disease This may occur also when rats are secondarily infected with several species of Salmonellae and Pasteurellae or when combined A and C avitaminoses are produced in the infected rodents

The duration of the latent infection following the disease has not yet been established however it may be long Mackehenie (1934) reported a case of an engineer who gave positive cultures 16 months after an attack of verruga and a patient with nervous symptoms who 6 months later yielded pure cultures of *B bacilliformis* Howe (1943a) obtained positive blood cultures from a person who had had the disease 5 years previously Most of these postconvalescent asymptomatic infections have been reported from people living in the endemic zone so that it is impossible to evaluate whether such cases represent single or repeated infections Postconvalescent asymptomatic infections may become apparent even after long periods of time although such cases appear to be ex

tremely rare Escomel (in Weinman 1944) reports a case of a patient who had had an attack of verruga then lived in Europe for 20 years upon his return to Peru and before he had passed through any known endemic zone a tumor developed on his toe this was a typical verruga with numerous demonstrable Bartonellae The patient stated that during his residence in Europe he had had similar tumors

Howe (1942 1943a) demonstrated the presence of specific agglutinins in the blood in cases during or after the disease In the noneruptive stages titers as high as 1 160 but usually 1 20 were found During the eruptive stage titers ranged from 1 80 to 1 320

PATHOLOGIC ANATOMY

Oroya Fever

Fatal cases of Oroya fever show at autopsy signs of an advanced anemia There is usually marked emaciation Disseminated petechiae may be observed in the subcutaneous tissue The lymph nodes are moderately but clearly en larged and when cut appear pink or reddish The spleen may be normal

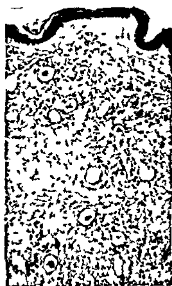

Fig 183 —Skin biopsy in Oroya fever showing cellular infiltration and vessels with agglo merates of *Bartonella bacilliformis* (Courtesy of Oscar Felsenfeld)

or slightly enlarged and may show numerous infarcts (Strong et al 1915) Hepatomegaly is sometimes observed Frequently the pericardium con tains a large amount of fluid serous in appearance (Groot et al 1941 Wein man 1944) Disseminated hemorrhagic petechiae may be found in different viscera

Microscopically besides the presence of Bartonellae in the red blood cells the most striking finding is the lesion observed in cells of the reticuloendothelial system The lesion consists of the development of Bartonellae within the cyto

the duration of the eruptive stage was 7 weeks in 2 cases, 8 weeks in 1 case, 9 weeks in 1 case, 12 weeks in 2 cases, and 20 weeks in 1 case (1939)

Frequently the eruptive elements appear in successive outbreaks, so that it is possible to find in the patient verrugas in different phases of evolution. The lesions heal without leaving a scar unless they have been secondarily infected.

The preceding description does not cover all the observable clinical cases, but it certainly applies to the large majority. Odriozola described some cases in which Oroya fever followed the eruptive stage. Likewise, forms with mild symptomatology and marked rheumatoid pains, which persist for months or years and which cease with the eruption of verrugas, have been reported, as well as cases of long duration in which the principal symptom was the repeated appearance of discrete eruptive lesions.

IMMUNITY

People who have had the disease and continue to live in endemic areas in most cases do not present second attacks of Carrión's disease. Certainly some cases of repeated attacks of verruga have been reported, but they are far from common. This leads us to think that in most cases a lasting immunity develops after the disease. From experimental data we know also that monkeys show resistance to reinoculations.

The numerous cases in which Bartonellae are found in the blood long after recovery from the disease indicate that the immunity which usually follows the clinical attack coexists, at least in some cases, with latent infection, and the presence of Bartonellae in healthy people without previous history of the disease shows that in these cases there is a balance between the infected man who cannot eradicate his infection and the infective agent which does not cause apparent disturbances in its host. This balance may be disturbed with the consequent development of Carrion's disease in the carrier, or, possibly, it may not be disturbed but the infection may remain completely asymptomatic throughout its course. This condition is similar to the state of premunition which exists in animal bartonellosis. In rats infected with *Haemobartonella muris*, the infection usually remains asymptomatic, but when such rats are splenectomized, the latent infection is changed into apparent disease. This may occur also when rats are secondarily infected with several species of Salmonellae and Pasteurellae, or when combined A and C avitaminoses are produced in the infected rodents.

The duration of the latent infection following the disease has not yet been established, however, it may be long. Mackehenie (1934) reported a case of an engineer who gave positive cultures 16 months after an attack of verruga, and a patient with "nervous symptoms" who, 6 months later, yielded pure cultures of *B bacilliformis*. Howe (1943a) obtained positive blood cultures from a person who had had the disease 5 years previously. Most of these postconvalescent asymptomatic infections have been reported from people living in the endemic zone, so that it is impossible to evaluate whether such cases represent single or repeated infections. Postconvalescent asymptomatic infections may become apparent even after long periods of time, although such cases appear to be ex-

are congested, with dilated sinuses Strong (1915) has reported ulcerations in the large intestine with distinct undermining of the mucosa at the edges These lesions occurred near capillaries with numerous infected endothelial cells

Eruptive Stage (Verruga)

The lesion consists of newly formed vessels of different sizes lying in connective tissue, with edematous zones, hemorrhagic foci, and a marked proliferation of the endothelial cells of the vessels Bartonellae are present in these proliferated cells They are rod shaped or form round masses However, these clusters are never as pronounced as in the organs in Oroya fever cases, and the distention of the infected cells is significantly less common than in Oroya fever (Pinkerton and Weinman, 1937) The epithelial cover of the verruga is thin

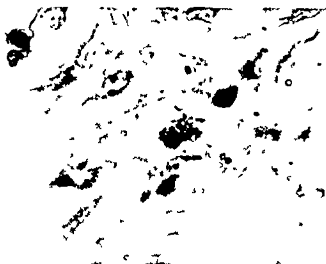

Fig 185—Section of a verruga *Bartonella bacilliformis* within the protoplasm of a macrophage Giemsa stain (×1280) (Photograph by C Sanmartin)

sometimes with signs of parakeratosis (Groot, Mayoral, and Martinez, 1941), and may be absent in some places, in which case it is replaced by a layer of fibrin and leucocytes At the periphery of the lesion the capillaries may be markedly dilated As the lesion progresses the connective tissue becomes more abundant and in some cases may present a fibrosarcomatous appearance When the verruga becomes older, the fibroblasts and the collagen fibrils increase in number The epithelial cover may be hypertrophied, and portions of cornified epithelium may be seen in the depth of the connective tissue mass (Strong, 1915, Groot et al, 1941) When secondarily infected, the lesions develop purulent foci

The histology of the subcutaneous nodules is similar to that of the cutaneous lesions The subcutaneous nodule is usually surrounded by a connective tissue capsule which sometimes sends thin walls into the mass of the lesion In its center, foci of necrosis may be found (Groot et al, 1941)

plasm of endothelial cells of sinusoids and of lymph and blood capillaries (Strong et al, 1915) Infected cells have been found in the lymph nodes, in the liver, bone marrow, spleen, kidney, intestines, adrenals, pancreas, in the skin, and occasionally in the heart and lung (Weinman, 1944) In the infected cells the Bartonellae sometimes are discrete and rod shaped as seen in more than 80 per cent of infected Kupffer cells of the liver (Pinkerton and Weinman, 1937), but in the remaining 20 per cent and in all other organs the microorganisms appear aggregated in granular or amorphous spheroidal masses which distend the cells, sometimes to an extreme degree Marked erythrophagocytosis by the Kupffer cells of the liver and the macrophages of the spleen is observed These cells also contain hemosiderin (Ash and Spitz, 1945)

Fig 184 —Section of a verruga. Hematoxylin eosin stain Low power (Photograph by C Sanmartin)

The liver presents areas of necrosis of the central type about the hepatic vein (Strong et al, 1915) Hurtado, Pons, and Merino (1938) have reported degeneration also around the central veins According to Weinman (1944), it is likely that such necroses are due to anoxemia Strong attributed them to a probable toxin, not yet isolated The spleen is congested, with infarcts, venous thromboses, marked erythrophagocytosis, and large amounts of pigment, yellow or yellowish brown, present within the macrophages as well as in free masses outside the cells This pigment does not give the iron reaction The bone marrow shows functional hyperactivity, that is, a transformation to red marrow of a great part of the yellow marrow of the long bones The enlarged lymph nodes

symptoms are low blood pressure, extreme tachycardia normal temperature with large numbers of Bartonellae in the blood, the appearance of complications such as pneumonia or salmonellosis, and the marked increase of urobilinogen in the urine The daily examination of the blood gives very useful data about the course of the disease and its possible termination Generally the degree of anemia is proportional to the seriousness of the prognosis, and a small number of reticulocytes is unfavorable The appearance of eosinophiles is usually considered as a good prognostic sign (Hurtado et al, 1938, Groot et al, 1941)

During the eruptive stage, recovery is the rule However, Odriozola (1898) has described some cases in which Oroya fever followed the appearance of verrugas, but such cases seem to be extremely rare In Colombia no deaths have been reported during the eruptive stage

TREATMENT

Several drugs have been used in the treatment of Oroya fever, almost always without significant beneficial effects Neoarsphenamine, Prontosil, sulfanilamide, sulfapyridine, neutral salts of acriflavin, quinine have not proved successful SDT 386, a Bayer arsenic and antimony compound, which has given good results in *Haemobartonella muris* infection of rats, is useless in Carrion's disease

Recently penicillin has been used Although the present data are not conclusive, there is some evidence that this antibiotic is helpful, at least in certain cases Castro (1945, 1946) treated 59 Oroya fever patients with doses between 100,000 and 2,000,000 units He states that in most cases there was a notable amelioration of the symptoms after the treatment Among the 59 patients, 10 died Castro has found a mortality of 40 per cent in untreated cases Aldana (1945, 1946), Aldana and Tisnado (1945), Robinson (1945), Vila y Acuña (1945), and Merino (1945) employed total doses ranging from 240 000 to 1,600,000 units, using a daily dose between 100,000 and 200 000 units Most of the patients received a total of 600,000 units When the treatment was begun, 13 patients had a marked degree of anemia Of their 14 Oroya fever patients, 3 died 1 because of a pneumonia complication, and 2 who were received for treatment with very severe anemia and in a markedly poor condition The authors report significant improvement of the clinical condition in the remaining 11 One of these 11, however, later developed salmonellosis and died The element of fever was improved in most cases and a marked drop in the number of Bartonellae in the peripheral blood was observed 8 to 72 hours after initiation of treatment Seven months after the penicillin treatment, none of the recovered patients had developed verrugas The number of these observations is small, however, the results seem encouraging

Howe (1943b) treated 3 cases with immune rabbit serum In such cases the degree of reduction of Bartonellae in the blood stream was more rapid than in the controls In 1 case the time in which the eruptive stage appeared after Oroya fever had receded was notably short

Weinman (1944) found in sections of apparently normal skin from a case of Oroya fever proliferated and infected endothelial cells together with large numbers of capillaries. The lesion thus appeared as the possible beginning of a verruga.

DIAGNOSIS

Noneruptive Stage

Demonstration of the causative agent in the peripheral blood makes the diagnosis and is essential for such a diagnosis. The procedures usually followed are the microscopic examination of stained films, both thin and thick, and when necessary, blood cultures in suitable media. When the disease is well established, the irregular fever, the rapid and severe anemia, the high erythrocytic sedimentation rate, the pains in the joints, the enlargement of the lymph nodes, the environment in which the patient has recently lived are all data of great value for a diagnosis.

However, early in the disease or when the disease runs a very mild course, the clinical manifestations are by no means marked and the Bartonellae might not be found by microscopic examination of the blood. In these cases it is necessary to make blood cultures. For this purpose the medium which has given the best results in the hands of the author is Geiman's semisolid medium (see above).

Eruptive Stage

The appearance of the verrugas is so characteristic that it is difficult to mistake the disease for any other. The clinical diagnosis may be confirmed by demonstration of the Bartonellae in the lesions. Sections should be prepared with Regaud's fixative stained later with Giemsa stain. The verruga may resemble an angioma, an angiofibroma or a botryomycoma. These tumors, however, are almost always single and congenital. Bassewitz described in Brazil "angiofibroma cutis circumscriptum contagiosum," a condition similar to verruga. So far the true nature of Bassewitz tumors has not been established and from present data there is not sufficient information on which to base a differential diagnosis.

The subcutaneous nodules, when they have not eroded the skin, may resemble fatty tumors, fibromata and similar pathologic conditions. However, the coexistence with typical miliary verrugas, the localization near the joints and the course of the disease furnish the diagnosis. In doubtful cases bacteriologic and histologic study of the lesions should be made.

In this period blood cultures are often positive.

The disease is not transmissible to the usual laboratory animals. Even monkeys are difficult to infect.

PROGNOSIS

When a patient presents the Oroya fever syndrome, prognosis is not good. The mortality in such cases is high, about 40 per cent. The individual prognosis depends upon the general state of the patient. Among bad prognostic

with a similarly prepared vaccine, 44 children in the village of Bolivar (Colombia) The vaccinated children and 45 unvaccinated controls were watched during the following 3 years Two cases of Carrion's disease were observed among the vaccinated individuals, and 6 cases among the controls During those 3 years, 10 per cent of the entire population of Bolivar presented Carrion's disease

Good nursing care and well balanced and adequate diet are essential The administration of ferrous sulfate liver extracts vitamins B_1 and C is usually recommended as accessory measures Blood transfusions are indicated especially when the anemia is marked These transfusions should be large and should be repeated frequently

The therapeutic measures during the eruptive stage tend to maintain the patient in good condition Care must be taken to prevent secondary infection of the verrugas Excision sometimes is indicated When this is the case it is preferable to await full growth before operating This occurs when the verrugas near the joints cause limitation of function of the limbs or when the lesions become gangrenous Vila y Acuna (1945) and Aldana and Tisnado (1946) have reported three cases of verrugas treated with penicillin They report that a marked improvement of the condition is observed and that the treatment hastens the improvement of the lesions One of the cases was treated after 4 months of development and cure was reported 2 weeks later In the second case after approximately 15 days of development treatment was given over 11 days and a few days later the patient was discharged with notable improvement In the third case after a period of 28 to 58 days the patient was treated for 10 days at the end of which many lesions had totally disappeared and no new eruptive elements had appeared

PROPHYLAXIS

From a theoretical standpoint 3 kinds of prophylactic and control measures might be considered (1) those intended to prevent Phlebotomi from biting man (2) those intended to destroy the insect vector (3) prophylactic immunization

In regard to the first staying after dusk only in Phlebotomus proof houses and departure from the endemic zone at night have been suggested To reduce sand flies DDT has been used recently and appears promising Hertig and Fisher (1945) found this insecticide effective against Phlebotomi in Italy and in the Dead Sea area Unfinished experiments in Colombia performed by Mondragon on a wide scale in two villages in the endemic area have shown so far a significant decrease in bartonellosis morbidity rate after the application of DDT

As far as prophylactic immunization is concerned the search for a possible effective vaccine has begun Very limited experiments have been performed though and the results cannot be considered as conclusive Howe and Hertig (1943) vaccinated a group of 22 previously unexposed volunteers who intended to establish residence in a highly endemic district The vaccine consisted of injection of a formol killed suspension of *B bacilliformis* which had been grown in German solid medium Out of the 22 volunteers 19 developed specific agglutinins with titers up to 1 160 after the vaccination After a variable time of residence in the verruga zone 12 of the vaccinated persons had positive blood cultures for *B bacilliformis* and developed mild systemic symptoms, such as slight fever arthralgias and headache Only one of these 12 patients had to be hospitalized but 5 later showed eruption of verrugas. The author vaccinated

latitude south where the average yearly temperature is 70° F The disease is almost unknown in the regions beyond 35 to 40 degrees N and 20 degrees S, although 160 cases have been recorded by Lichtman (1947) in Durban, Natal, Union of South Africa, at 30 degrees S There are very few cases above an altitude of 1500 feet above sea level The countries where ulcers have been found are given below

Equatorial Africa—Gold Coast, Kenya, Mozambique, Sierra Leone, Liberia, Gambia, Nigeria, Northern Rhodesia, Oran, Nyasaland, Tanganyika, Uganda, Sudan, Zambezi, Algeria, Belgian Congo, Somaliland, Tripoli, Libya, and Madagascar

Central and South America—British Guiana, San Domingo, Jamaica, Trinidad, Argentina, and Brazil

Asia—Syria, Aden, Israeli, Persia, Red Sea Islands, India, Burma, Federated Malay States, Yemen, Java, Siam, *Singapore, Indonesia, Indo China, Melanesia, Philippine Islands,* New Guinea, and southern China

Europe—Caucasia

In many tea districts of Assam and Cachar in India, the disease is endemic, occurring almost every year and sometimes in an epidemic form

Hughes states that in Assam, India, 35 to 40 per cent of the labor population in the tea gardens is temporarily disabled Charters (1947) found, among 292 Somali soldiers admitted, no less than 143 affected with tropical ulcer Grenoilleau (1946) actually recorded 7,923 cases in 1943 and thought that there were likely to be 57,401 actual cases Though the diagnosis of all kinds of ulcers is not given, there is little doubt that the majority belonged to the phagedenic type According to Manson Bahr (1940), the ulcer is a great scourge in the Solomon Islands and indeed in the whole of Melanesia

It is clear from all these records that the disease is important from the standpoint of public health

Season and Epidemiology

Most cases occur when the weather is hot and humid Clements (1936) noted the highest incidence in New Guinea towards the end of the rainy season when the soil was still damp Roy (1928) records the maximum incidence in July in Assam, when there is usually *very heavy rain Abundant rainfall and warm and damp soil are favorable factors* Panja (1945) noted in July to December of 1943 a large number of cases occurring in Calcutta. Grenoilleau (1946) records an epidemic beginning in July and subsiding at the end of December He goes on to state that the seasonal character of the disease is of an estivo autumnal type

Pattanayak (1944) notes the highest peak in August and September, whereas Nath (1946) finds the highest incidence in October to December Luthra (1946) found cases for 2 months after the rains in the Punjab

From a consideration of all the data, it is evident that the epidemic is prevalent in the rainy season and for 2 to 3 months in the postmonsoon period, and it gradually disappears as winter approaches There is one peculiarity in the epidemiology of the disease It is endemic in certain localities, for example, Assam in India, whence the epidemic spreads in some years Cases were unknown in Bengal for many years, but in 1943 an epidemic spread not only in Bengal but almost all over India including Bombay, Gujrat, Madras, Central Provinces, Orissa, and Punjab, etc As usual, there is also a periodicity in the epidemic There were many [illegible]
in 1943 to 1946 I [illegible]
through the end of [illegible]
average daily 50 admissions into hospitals was recorded, the highest peak was in the middle of October In fact, the disease affected the population, including Europeans, especially the womenfolk, to such a degree that it amounted to a veritable scourge (Grenoilleau, 1946) In some years in Assam, according to Hughes (1931), as already stated, 35 to 40 per cent of the coolie population is affected in the tea gardens at Sylhet Roy (1928) records average duration of absence from duty in a year in a garden at Sylhet at 41 4 days and consequently

CHAPTER 33

TROPICAL PHAGEDENIC ULCER (VINCENT'S ULCER)

GANAPATI PANJA

Synonyms.—Ulcus tropicum, tropical ulcer, Naga sore (Assam, India), Cachar boil, Malabar ulcer, Jungle Ghao, Gala (Gwalior, India) Annam ulcer, Cochin sore, Aden ulcer, Yemen ulcer, Mozambique ulcer, Delago sore, Natal sore, Rhodesian sore, Zambesi sore, tropischer phagedenismus (German), Ulcère phagédenique des pays chauds (French), Goyana ulcer, Chaco ulcer (Argentina), Tropical sloughing phagedaena

The best name should be either "tropical phagedenic ulcer" or Vincent's ulcer, as the word "phagedenic" means 'eating canker" and such a phagedenic condition with presence of copious slough and Vincent's fusiform bacilli is characteristic of the ulcer

The simple name "tropical ulcer" is misleading as there are, in the tropics, many ulcers free from phagedena and fusiform bacilli Tropical ulcers described by Golden and Padilla (1946) at Guatemala are not the phagedenic ulcers There is no exudate in a 2 week old ulcer and no fusiform bacilli found in any case

Ulcers described by Dostrovsky and Sagher (1946) at Palestine are probably not tropical phagedenic ulcers These are neither oval nor circular are surrounded by superficial detachment of epidermis, and are free from fusiform bacilli

There are sloughing ulcers in the tropics but without any fusiform bacilli These are not tropical phagedenic ulcers Hence the very best name should be Vincent's ulcer Costa (1944) has also suggested the same name

The earliest record of the disease is found in a Burma expedition recorded in James Annesley's *Researches Into the Cause, Nature and Treatment of the More Prevalent Diseases of India* (1828) The disease was known in Algiers (North Africa) in 1896

DEFINITION

It is an acute specific ulcer, single or multiple, circular or oval, punched out and excavated, with indurated and raised borders varying in size from 1/4 to 2½ inches in diameter confined mostly to the lower legs feet and toes, associated with copious and often fetid pus, tenacious slough, sero sanguineous discharge pain and a tenderness and rarely accompanied by enlarged neighboring glands fever, and constitutional symptoms The ulcer develops later into a chronic stage without the foregoing typical features

ETIOLOGY

Geographic Distribution and Incidence

This has been well shown by Clements (1936) It is very interesting to note that the ulcer is found more often near the Equator in tropical and subtropical countries that are included in a belt drawn around the globe between the 35th latitude north and the 10th

on the disease are unanimous in acclaiming trauma as being the starting point in most cases Trauma or skin disease also reduces the reduction potential of tissues and thus favors the development of a sore by subsequent infection

Diet

Much attention has been paid to diet as being the possible cause of the disease Some workers regard general malnutrition as an essential factor

McCulloch et al (1928) and Brown (1935) laid the etiology on low protein and fat high carbohydrate, and inadequate vitamin supply Clements (1936) carried on a careful observation of the diet in New Guinea and came to the conclusion that deficiency of the vitamin B complex associated with diet rich in carbohydrates but low in protein and fat was undoubtedly a predisposing factor Farle (1942), on the other hand, thought nicotinic acid was the important factor Almost similar results were obtained by Orr and Gilks (1931) in East Africa and Burnie (1931) in Nigeria Edge (1921) considered the condition to be a deficiency disease Scott (1941) and Charters (1943) laid stress on deficiency in vitamin A as being the precursor of the production in tropical ulcer The latter tested improvements in ulcers by giving calcium, codliver oil, and milk, and comparing results with a control group, but his number of cases was so small that no statistical significance can be attached to his results Corkill (1939) also does not agree with his results and says that vitamin A improves the rate of healing of many kinds of ulcers Moreover, it has been found that healing takes place in an average number of 45 days when vitamin A is given and at the same time the ulcers are dressed with codliver oil In the control group, however, when the ulcers are only dressed with zipp and no vitamin given, the average number of days is less, that is, 39 days Blank (1947) was of the opinion that vitamin B deficiency was an important predisposing cause and called the malady a "poor man's disease" Lichtman (1947), in Natal, considered the condition to be mainly nutritional in origin He found the disease strikingly seasonal In autumn, the diet of the people consisted mainly of maize and the disease was in its highest peak in May, but in winter people had cattle flesh as well with the result that the disease disappeared Calcium deficiency has been cited by Brown (1935) and Loewenthal (1932) as an important predisposing cause Brown found daily intravenous calcium chloride definitely beneficial Loewenthal gave intravenous calcium chloride, 15 grains in 10 c.c of distilled water daily, and found 52 per cent cured and 32 per cent improved On the other hand, Brown (1935), Clements (1936), and Farle (1942) did not find any deficiency in calcium in the blood

It may be stated here that if calcium deficiency or malnutrition is the important cause, these questions arise Why do the ulcers occur mainly on the lower legs? Why does penicillin cure all cases even if associated conditions are neglected? There are many other workers who have strong reasons to believe that malnutrition is not the important cause

Patterson (1908), with his wide experience, found the disease in healthy persons as well Buchanan and Sanderson (1935), in Africa, found no favorable response to diet rich in vitamins Hughes (1931) noted no improvement by feeding with codliver oil, orange juice, and yeasts Marsh and Wilson (1945) remarked that most of their cases healed even though slowly, in spite of their dietetic errors In Panja's (1945) series of 61 cases, malnutrition was noted in but 4 cases, 57 cases were in good health

The author's position is based upon the following facts

1 The disease was not seen in Calcutta for years prior to the epidemic of 1943 although dietetic deficiency had long been common

2 The disease was seasonal and the epidemic subsided in spite of the prevailing dietary deficiency

a great economic loss is sustained by the tea garden companies Patterson (1908) remarked "This year the typical phagedenic ulcers have swept like a plague up the whole of Assam on both banks of the Brahmaputra River and have temporarily incapacitated many thousands of coolies "

Age

The disease is common in young adults engaged in active occupation Roy (1928) records the disease in 99 6 per cent of adults and 0 4 per cent of children and infants Ghose (1934) found the disease in only 3 children out of 69 cases In the Calcutta epidemic recorded by Panja (1945) no young children and infants were found affected Clements (1936) notes the highest incidence in ages 10 to 40 among 250 cases studied and remarks that children under 5 years are scarcely affected Pandit (1946) writes that the largest number of patients falls in the age group of 10 to 30 years

From all these records it can be concluded that the largest number of victims falls in the age group of 10 to 36 years Cases are extremely rare below the age of 5 and old people are scarcely affected

Sex

The disease has a higher incidence in males, and it may be 6 times more frequent than in females

It is interesting to note that in certain tea gardens of Assam the female population is more often affected This might be due to the fact that the laboring population in those gardens consists of a preponderance of females Grenouilleau (1946) in Algeria, records women victims more often among 85% European cases and suggests bare legs (without stockings) as being the predisposing cause of infection

Occupation and Nationality

Occupation is a very important predisposing cause Barefooted laboring classes are the most frequent victims in the tea gardens of India Hughes states that in Assam 35 to 40 per cent of the labor population is temporarily disabled during the busiest season of the year This fact alone suggests the possibility of an infection attacking the legs from the soil Besides occupation leads often to trauma which favors the entry of infection as will be shown later on Europeans are not barefooted and do not go about in the mud It is mainly for this reason that they are very rarely affected In India not a single case among Europeans is recorded although they are in close association with the labor population in the tea gardens. The better class Indians who have clean habits wear shoes and do not work in the fields escape the disease As stated above Grenouilleau (1946) in Africa recorded many cases among Europeans especially women The reason put forward by him is that women although they wear shoes have their lower legs exposed to insect bites scratches etc and this allows entrance of infection from the soil

Trauma

Trauma is a very important predisposing cause and may take the form of abrasions cuts puncture wounds mosquito or leech bites, burns injection thorn pricks smallpox vaccination or skin diseases such as impetigo boils, pustules trophic ulcers of leprosy etc Most of the cases give history of trauma in some form or other It has also been proved experimentally that trauma is necessary for the production of a sore

Clements (1936) in his series of 179 cases found sores in 114 cases definitely traumatic in origin Burnie (1931 in 250 cases noted ulcers occurring at the sites of injury in 244 cases Fox (1932) found sores developing at the sites of inoculation of cholera vaccine in 14 coolies Blanchard (1914) recorded ulcers on vaccination pustules Almost all the writers

BACTERIOLOGY

The bacteriology of this disease has been studied in detail by a number of workers When a film of pus from a typical ulcer is examined from day to day by staining with Gram's Leishman's, Giemsa's, and Ziehl Neelsen's stains, gram positive fusiform bacilli are always found Vincent's spirochetes are found in some ulcers Gram positive cocci, diphtheroids, and gram negative bacilli are sometimes found No acid fast bacilli or protozoa are seen

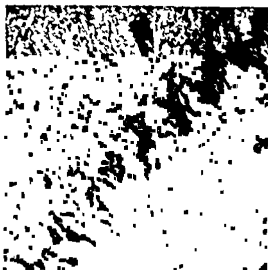

Fig 186 —Section of Naga sore showing the row of fusiform bacilli in the depth of the ulcer

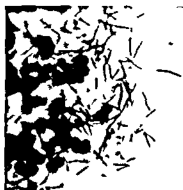

Fig 187 —Smear from Naga sore showing fusiform bacilli

It is claimed that Le Dantec (1884) was the first to find the Vincent bacillus (fusiform bacillus) Vincent (1896) found fusiform bacillus and spirillum in 40 out of 47 Arabian tourists suffering from the disease Blanchard (1905) and von Prowazek (1907) attributed the cause of the ulcers to the spirochetes Noguchi considered the spirochete to be the same as *Treponema vincenti* Keysselitz and Mayer (1909), working in Africa, were perhaps the first to describe fully the fusiform bacilli and the spirochetes Apostolides (1922), in Smyrna, studied 202 cases and was of the opinion that the only causative agent, the sine qua non of tropical ulcer, was the fusiform bacillus in association with *Spirochaeta schaudinni* Roy (1928), in Assam, in his study of 386 ulcers, found

3 Ulcers occurred in the majority of persons with no signs or history of dietary deficiency

4 In a family when one member was affected others were rarely affected, although the same dietetic conditions prevailed

5 Ulcers were invariably limited to the lower legs Other parts of the body ought to have been affected as well if dietary deficiency was the cause

6 Healthy volunteers were successfully inoculated with the ulcer material or cultures of the fusiform bacilli

7 Ulcers in all cases responded well to treatment with copper sulfate or penicillin but not to supplementary diet

Manson Bahr reports that he has treated several severe cases in healthy and well fed Europeans Pattanayak (1944) found a number of healthy or robust persons developing tropical ulcers Pandit (1946, 1947) working in an endemic area for 3 years did not notice malnutrition in any case Roy (1928) in his study of a large number of cases in the tea gardens does not consider malnutrition to be the chief predisposing cause Bharucha (1943) had 179 patients all Indian soldiers receiving a uniform diet as laid down by Army authority, not known to be deficient in any essential constituents

It is clear from all these reports that diet calcium or vitamin deficiencies are not essential predisposing causes

Associated Diseases and Debility

Associated diseases and debility have been cited by various workers and much stress has been laid particularly on malaria and hookworm infections as possible predisposing causes Manson Bahr has pointed out that the distribution of the disease follows that of malaria Malaria however is rampant every year in the villages of Bengal in India but tropical ulcer is unknown there for years Patterson (1908), with his vast experience in Assam was convinced that malaria kala azar and debilitating conditions did not influence this disease Bharucha (1943) wrote that associated diseases such as malaria dysentery anemia and avitaminoses were not present in an active form in his 179 cases Marsh and Wilson (1945) believe that even if associated diseases are neglected the ulcers will heal with proper local treatment It is not reasonable to place the blame on the associated diseases when epidemics of the disease occur in certain seasons and treatment with penicillin cures all cases in spite of nontreatment of associated diseases Such diseases of course lower the vitality and tend to prolong the course and severity of the disease

The important causes can be summarized in the alliterative words of Marsh and Wilson (1945) all beginning with the letter "F" "Filth Food Friction and Fusospirillosis" Infection with the fusiform bacilli is the major factor as will be shown later Under the present state of our knowledge spirochetes cannot be incriminated in the etiology Lack of cleanliness is certainly a more contributory factor than friction or injury for even after implantation of the fusiform bacilli through injury if proper care is taken the disease is very likely to be prevented Lack of food that is, malnutrition, lowers the vitality and may render patients liable to infection, proof of this is not yet established however There is of course no doubt that when once a person is attacked malnutrition and debility will prolong the course and severity of the disease

serum agar, by Slanetz and Rettger (1933) on blood or potato extract agar with gentian violet under an atmosphere of 2 per cent carbon dioxide gas, by Smith (1933) on sheep serum agar with a fragment of ulcer tissue and poured plate method Most of the workers obtained, in 3 to 5 days, fine colonies like those of Streptococci, with irregular edges

Microscopically, Krumwiede and Pratt described the bacilli as slightly curved, with *tapering ends, sometimes* filamentous or in long chains, gram negative, nonmotile, and fermenting galactose and saccharose, with a foul odor in cultures Bergey describes the fusobacterium as gram negative rods with tapering ends, usually nonmotile, and showing granules in the body With Giemsa stain, the bacilli are light brown with maroon colored granules (Fox, 1921)

More recently Panja (1945) successfully cultivated the fusiform bacilli anaerobically on sheep blood agar in which he incorporated a little sterilized pus from tropical ulcers. A thick inoculum was streaked on blood agar slope or plate Fine, translucent colonies were seen after 3 to 4 days' incubation at 37° C The majority of the cultures were viable for 7 to 10 days only Solidified serum or egg medium was found liquefied when it was inoculated with pus containing fusiform bacilli Microscopically, the organism was sometimes seen to be motile, showing brisk, twisting, and sometimes a circling movement It was gram negative, fusiform, arranged either singly or in pairs or in chains characteristically clustered Seshadrinathan (1945) obtained pure cultures of the bacilli on 1 per cent nutrient agar incorporated with 25 per cent rabbit blood in an atmosphere of 90 per cent hydrogen and 10 per cent carbon dioxide at 37° C by the cup technic He put fine emulsion of pus made in normal saline into the cup and obtained transparent fine colonies a little away from the cup, but his subculture was not successful Pandit (1946, 1947) reported cultivation of the fusiform bacilli from tropical ulcer on blood agar in an atmosphere of hydrogen and 5 per cent carbon dioxide gas Colonies are fine like Streptococci

The bacillus is a strict anaerobe, gram negative, nonmotile, pleomorphic, does not ferment any ordinary serum sugars, but produces indol The organism does not grow well on Slanetz and Rettger's (1933) medium, although the fusiform bacilli from the mouth grow very well on this medium These differ in morphology and colony characteristics from the fusiform bacilli of tropical ulcer Varney (1927) classified the fusiform bacilli isolated from various sources into four types His type III is almost similar to Panja's culture, that is, gram negative, slightly curved individual bacilli or occurring in long wavy chains and huge clusters

Spirochetes—E C Smith (1930) cultivated the spirochetes on modified Wenyon's human blood saline agar under aerobic conditions in 48 hours at 37° C

A number of workers have noted fusiform bacilli changing into spirillary forms and vice versa Tunnicliff (1906) noted in the culture of fusiform bacilli filamentous and spirillary forms Sanarelli (1927) regarded spirochetes and fusiform bacilli as different forms of the same organism In fact, he was able to change one from the other and vice versa D T Smith (1932) repeatedly found fusiform bacilli changing into spirochetal forms Smith (1933) sometimes found nonmotile spirochetal forms in third day old culture of fusiform bacilli Tunnicliff (1933) noted colonies of fusiform bacilli after the fifth day of culture changing into rough forms Microscopically, such rough colonies were found to contain spiral forms of the bacilli Tunnicliff and Hammond (1934) made a careful study of the rough colonies of fusiform bacilli and came to the conclusion that the fusiform bacillus and the spirillum were different forms of the same parasite Panja (1945) found fine colonies of pure spirillary forms on repeated subculture changing into the usual colony forms of fusiform bacilli but his spirillary forms did not resemble Vincent's spirochetes Pandit (1946, 1947), on the other hand, did not obtain transformation of fusiform bacilli into spirochetal forms It is therefore not yet definitely settled whether the fusiform bacilli and spirochetes are different forms of the same parasite

Experimental Production of Tropical Ulcer

1 **With Pus**—Experimental production of ulcer in man with pus from tropical phagedenic ulcers was tried by various workers Cross (1900), P Blanchard (1914), Balli

fusiform bacilli in only 120, and in about one half the number on repeated examination Spirochetes were found in only 7 Besides, he observed gram positive diplococci in the ulcers He was inclined, therefore, to suggest that the diplococci might be the causal organisms and fusiform bacilli were secondary invaders It might be said here that not a single worker up to this day has corroborated his finding of diplococci Panja (1945) found besides fusiform bacilli organisms such as cocci, diphtheroid bacilli gram negative bacteria and sometimes Clostridia but there was no constant association between any of these organisms and active stage of the ulcer except with the fusiform bacilli

Panja (1932, 1937 1938 1943) found fusiform bacilli in all his cases and suggested that their presence was a criterion for diagnosis A fact of great importance in some of his cases was that in 17 ulcers, fusiform bacilli alone were found by him on repeated microscopic examinations and no other organisms were detected by aerobic culture using blood agar The fusiform bacilli seemed to disappear when the ulcers were healing but reappeared when healing was interfered with by artificial means A constant association was noted by him between the presence of fusiform bacilli and the characteristics of a typical phagedenic ulcer

Fig 188 —Leptothricial forms of fusiform bacilli as seen in Naga sore pus under oil immersion objective

The overwhelming evidence is that fusiform bacilli are constantly associated with tropical ulcers and spirochetes only partially These latter may either be living in symbiosis with the bacilli or may represent some stage in the development of the bacilli There are some proofs, as will be shown later on in support of this latter proposition The absence of fusiform bacilli in a few cases can be explained by the following facts that such ulcers may not be tropical ulcers at all that the ulcers may be in the healing stage when search for the bacilli is made and that a thorough search for the bacilli has not been undertaken from day to day

Fusiform bacilli have also been found often in the undermined edges of ulcers whereas none has been seen from the surface of such ulcers

Cultivation of Fusiform Bacilli and Spirochetes

Fusiform Bacilli —Fusiform bacilli are reported to have been successfully cultivated years ago under anaerobic conditions by Weaver and Tunnicliff (1905) on horse serum agar, by Tunnicliff (1906 1911 on ascitic agar slants, by Peters (1911) on Dorset's egg medium by Krumwiede and Pratt (1913) on horse serum agar by their special inverted Petri dish method of anaerobiosis by [illegible] et al. (1919), by Panja (1932) on gelatin

copious pus and typical gram negative fusiform bacilli, seen not only in films but also in pure state by culture He could not find any spirochetes or other microorganisms in any stage of the reproduced ulcer Ulcers healed in 10 to 20 days without any treatment except a sterile dressing Cultures from experimental sores yielded a pure growth of fusiform bacilli, and with subcultures from the artificial sores further tropical ulcers were reproduced Ulcers were also produced with a mixture of fusiform bacilli and Streptococci and such ulcers were larger and took a longer time to heal As he did not find spirochetes in the ulcers in any of his cases he had no occasion to try cultures of spirochetes and inoculation experiments with these Small doses of cultures of *Staphylococcus aureus Streptococcus pyogenes* diphtheroids and *Pseudomonas aeruginosa* that were isolated from some natural ulcers were injected intradermally into volunteers followed by crushing of the tissues at the site of inoculation but no typical tropical ulcer with presence of fusiform bacilli could be reproduced His key notes of success were heavy inoculum intradermal injection, repeated crushing of tissues after inoculation and application of bandage to prevent access of air and light

Vincent (1945) reproduced ulcers with cultures of fusiform bacillus in guinea pigs and rabbits by previously crushing the tissues at the site of inoculation and reproduced larger ulcers when Staphylococcus Streptococcus and Pseudomonas were mixed with the culture of fusiform bacillus He therefore came to the conclusion that the tropical ulcer was caused by fusiform bacilli frequently in association with *Borrelia vincentii* and other microorganisms especially Staphylococcus and Streptococcus Pandit (1946 1947) with great difficulty succeeded in obtaining a pure culture of the fusiform bacillus on blood agar in an atmosphere of hydrogen and 5 per cent carbon dioxide gas with a thick suspension of fresh culture he inoculated 5 volunteers intradermally but did not succeed in reproducing the ulcer His failure appears to be due to the fact that he probably did not repeatedly crush the tissues at the site of inoculation nor cover with a bandage

Serology

Panja (1945) found fusiform bacilli isolated from ulcers agglutinable with the rabbit sera against several strains of the bacilli, agglutinins were also found in some sera during recovery As the bacilli were autoagglutinable slide agglutination test with fresh cultures were carefully conducted

Summary of the Facts on Bacteriology

On reviewing all this research on the etiology of the disease a tentative conclusion can be made An infection is the major factor in the causation of the disease though Blank (1947) has raised the question as to why thousands of American troops working in the endemic area of Assam escaped the disease and why there was no infection transmitted from one person to another This can easily be explained by the fact that the fusiform bacillus is a strict anaerobe and cannot therefore multiply in an unbroken and clean skin Even if the bacillus is implanted on an injured skin it cannot produce an ulcer if care is taken of the injury at the beginning American troops know very well how to take care of their injuries That the fusiform bacillus is the true cause of the disease is established by the following evidences given by Panja (1945)

1 Fusiform bacilli are constantly associated with typical active tropical phagedenic ulcers and no other ulcers No such constant association is seen with spirochetes or any other microorganisms that are sometimes found in the ulcers

ano (1916), Shillong (1919), Fox (1921), Pampana (1923) Burnie (1931), Panja (1932, 1945), and Pandit (1946) succeeded in reproducing ulcers in human volunteers by inoculating them with the pus from tropical sores Blanchard's first attempt was unsuccessful, but in his second series of cases he succeeded by first necrotizing the skin with concentrated potassium hydroxide solution and 5 days later applying the pus on the necrotic area Apostolides (1922) records the case of a nurse whose forearm was scratched with an infected knife that had been used to incise a tropical ulcer 2 hours previously An ulcer similar to tropical ulcer developed at the site of the scratch Panja inoculated the arms and legs of volunteers intradermally with the pus and covered with a sterile dressing On the third day, a pustule formed, within 7 days, a typical ulcer showing fusiform bacilli developed In some of his cases, he performed the very important experiment of using samples of pus showing only fusiform bacilli on microscopic as well as cultural examination and succeeding in reproducing the ulcer The filtrate of such pus was found non infectious The same was corroborated by Pandit He also applied such pus on ordinary ulcers and found that typical tropical ulcer developed in a few days On the other hand, workers such as Sen (1922), Ruge et al (1925), and Smith (1933) failed to reproduce the ulcers Still, on the basis of accumulative evidences of expert workers, there is little doubt that the pus from a typical tropical ulcer showing fusiform bacilli is infectious to man and, when inoculated either on arms or legs, can reproduce typical ulcers showing the fusiform bacilli

As regards experimental reproduction of ulcers in animals, the majority of workers have failed

2 **With Cultures**—As very few workers have succeeded in obtaining a pure culture of the fusiform bacilli or spirochetes on laboratory media attempts at reproducing ulcers with cultures of the bacilli or spirochetes have not been undertaken on a large scale Fox (1921), in India, inoculated men with impure culture of fusiform bacilli, his experimental ulcers were atypical "not at all like the Naga sore," in his own words Panja (1932), in Calcutta, applied pure cultures from gelatin serum agar to scarified skin without any success, but when the culture was mixed with gram positive cocci or diphtheroid bacilli, an ulcer was reproduced but lasted for a few days only Smith (1933), in Africa, tried inoculation experiments on 8 volunteers with a pure culture of the bacilli isolated by him Boil like lesions developed in 2 cases only, typical ulcer in none, and ulcers regressed in 2 to 5 days showing only scanty fusiform bacilli

Smith (1930) believed Spironema to be the cause He reported he had succeeded in culturing the organism in modified Wenyon s blood saline agar His culture consisted of spirochetes, fusiform bacilli and *Pseudomonas aeruginosa* With this mixture he reproduced ulcers showing fusiform bacilli and spirochetes His culture was, therefore, not pure and his results were not confirmed by Brown (1935) Berry (1943) carried on an interesting observation for 3 years in the school children in Nyasaland He noted that when abrasions on the skin of the children were infected with cocci, no ulcers occurred, but when infected with cocci as well as fusiform bacilli typical ulcers were seen He also found a preponderance of fusiform bacilli on the skin during the rainy season This he supposed to be due to dampness and flies

Panja (1945), during the epidemic of 1943 in cases of tropical ulcer in Calcutta, repeated his previous finding (1932) He succeeded in obtaining pure colonies of fusiform bacilli like those of Streptococci on his "pus" blood agar medium, and later on ordinary freshly prepared sheep blood agar He inoculated 11 apparently healthy volunteers intradermally either on the upper arm or lower leg with 0 2 c c of a thick suspension of 5 different strains of pure cultures of fusiform bacilli in the third or fourth generation The site of inoculation was squeezed hard with a pair of sterilized forceps immediately after inoculation and on 2 subsequent days so as to crush the tissue and produce the required oxidation reduction potential for multiplication of the fusiform bacilli, a sterile dressing was kept on the lesion In all the cases ulcers developed, preceded by a purulent bleb and marked edema and tenderness at the sites of inoculation varying from one half to 1 inch in diameter within 4 to 6 days. Fever with rigor and edema of the whole limb were present at the beginning in some cases, but these soon subsided, leaving only an ulcer discharging

corroborate this It is interesting to make a note of a very early observation made by Young (1932) that the termite (a white ant) may be the reservoir of infection He found the ant harbored the fusiform bacilli but his observation has not been confirmed

Mode of Infection

Clements (1936) has suggested that spitting or application of saliva or chewed grass to wounds transmits the infection from the mouth Flies have been reported as probable vectors by Patterson (1908), Fox (1921) and Grenoilleau (1946) but no support is given to this mode of transmission by Roy Panja and Pandit Patterson believes that the eye gnat which has close seasonal coincidence with the ulcer may be responsible for spread of the disease Roy (1928) on the other hand carried on artificial experiments in Assam with mango flies and eye gnats (*Siphunculina funicola*) fed on tropical ulcer he concluded that such gnats were incapable of producing ulcers on scratches and could not play a prominent part in an outbreak He suggested that the prick of the shrubby herb (Mimosa), which is abundantly present in the tea gardens might carry the infection from the soil to the skin

HISTOPATHOLOGY

Histopathology has been studied in detail particularly by Keysselitz and Mayer (1909) Wolbach and Todd (1912) J C Smith (1932) Clements (1936) Panja (1945) and Pandit (1947) In the homogeneous upper layers of the

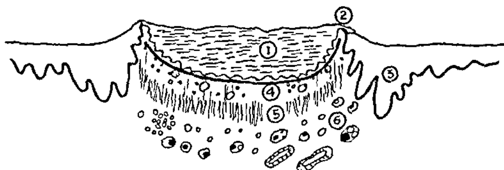

Fig 189—Naga sore diagnostic section *1* slough *2*, elevated edge *3* acanthosis in the prickle cell layer *4* vascular granulation tissue *5* felted mass of fusiform bacilli *6*, granulation tissue—plasma cells endothelial cells eosinophilic cells red blood cells—reaching up to sweat glands

ulcer composed of pus and slough pus cells red blood cells fibrin fusiform bacilli often pyogenic organisms and sometimes spirochetes are found In the deeper layers an extensive coagulation necrosis is seen in the form of a pseudomembrane Next to this that is a little below the floor of the ulcer a dense palisade' of fusiform bacilli forms a diagnostic picture Below this row of fusiform bacilli there exists a dense and very thick layer of vascular granulation tissue and polymorphonuclear leucocytes Wolbach and Todd noted also an extensive plasma cell infiltration They also found (Levaditi s

2 In some tropical ulcers fusiform bacilli only are found by microscopic and cultural examination and no other microorganisms either by microscopic or aerobic cultural examination

3 On histologic examination as will be shown later in the chapter fusiform bacilli have penetrated into the deeper layers of the ulcer while secondary invaders are found more superficially

4 The disease is reproducible in a number of human volunteers with pure primary as well as the third or fourth subculture of the organism under a special technic and the organism is recoverable in pure culture from experimental ulcers Ulcers are also reproduced with cultures of the organism isolated from experimental sores Koch s postulates are thus fulfilled

5 The disease may also be reproducible in animals if suitable precautions are taken

6 No evidences of a virus are found in the ulcer

7 Malnutrition deficiencies debility associated diseases and local infections with organisms other than the fusiform bacilli prolong the course of the disease

8 Infection as will be shown later is derived from the soil and the grasses, therefore the barefooted laborers are more commonly affected during the monsoon and postmonsoon months when they are engaged in active work

9 Infection enters through some break in the skin caused either by trauma or skin disease Poor laborers often acquire the disease because (a) they are more liable to injuries during work and (b) they do not take care of their injuries

Reservoir of Infection

Apostolides (1922) and Clements (1936) put forward evidence regarding human mouths as possible sources of fusospirochetal infection But Panja (1945) found the gums of most of his cases healthy and was not convinced of the possibility of infection from the mouth Pandit (1947) went still further and demonstrated that the mouth fusiform bacilli were different from the fusiform bacilli of tropical ulcers in their morphology colony characters and the ease with which they are cultivatable on Slanetz and Rettger s (1933) medium Roy (1928) has suggested that the soil may be the source of infection He found cases of clean ulcers without any fusiform bacilli returning with slough and fetid odor and full of fusiform bacilli when the patients were allowed to go about in the mud without any surgical dressing Panja also suspected the soil as the source of infection and went on to say that the infected soil from the endemic areas of Assam was carried during the war by the wheels of motor lorries plying incessantly from Assam to Bengal Grenoilleau (1946) is reported to have actually found the fusiform bacilli in the soil particularly when wet Napier (1947) in his book on tropical medicine states that the bacilli remain below the superficial soil in the dry season but come out on the top with the mud in the rainy season There is no doubt that the soil theory is attractive, but further experimental proofs are necessary to

Starting Point—The ulcer starts most commonly in some form of trauma—cuts, abrasions, bites, or some skin disease. Mohanty (1945) gives his figures in 76 ulcers from 36 cases thus: 29 on abrasions, 12 on blebs due to tight shoes, 6 on superficial cuts, 3 on boils, 25 on scabies, and 1 on burn.

Number—Ulcers may be single or multiple. Some authors found single ulcers in 90 per cent of their cases. Panja (1945) found single ulcers in 35 cases out of 61, and Pandit (1947) in 50 cases out of 75. Multiple ulcers may be from 2 to 20. Delsarma (1945) found 14 in 1 case. Panja found 16 in 1 case and 20 in another.

Fig 190—Ulcus tropicum 1 year

Size—The size varies from that of a pea to more than 2 inches in diameter. The majority are from 1/6 to 2½ inches (Luthra 1946 ½ inch to 3½ inches, Seshadrinathan ¼ inch to 3½ inches). The largest size recorded by Rao (1946) is 4 by 12 inches and by Luthra 5 by 10 inches.

Shape—Circular or oval, more often circular, and sometimes so nearly perfectly circular as if marked out with a compass.

Edge—Raised, undermined and bluish red. The ulcer has a cup shaped appearance. The surrounding tissue is generally normal but in early cases is edematous and red.

stain) spirochetes in the granulation tissue at a considerable depth below the surface of the ulcer Keysselitz and Mayer confirmed this finding Smith by practicing two kinds of staining—one by the Warthin method and the other by dilute Giemsa stain—demonstrated spirochetes ahead of the row of fusiform bacilli invading to a considerable depth the granulation tissue at the base He found the Malpighian layer of the epidermis in the neighborhood of the ulcer margin densely infiltrated with spirochetes Spirochetes were also observed by him in the walls of small blood vessels Costa (1944) also demonstrated spirochetes in the depth of the ulcer At the margins of the ulcer there is marked acanthosis that is an extensive proliferation of the rete It is interesting to note that Clements found the above histologic changes in his experimental ulcers also in rats

When an ulcer is in the chronic indolent stage these histologic changes are not found except for the presence of granulation tissue and newly formed fibrous tissue Golden and Padilla (1946) in their very careful and excellent histologic study demonstrated widespread damage of arterial and venous supply resulting in stenosis of lumina but unfortunately the ulcers they investigated at Guatemala were not typical phagedenic ulcers showing copious pus and fusiform bacilli

CLINICAL PICTURE

As a rule the typical clinical picture in the active stage of the disease presents itself in the form of a painful ulcer circular or oval 1 inch to 2½ inches in diameter The ulcer is full of copious and sometimes foul smelling grayish yellow blood tinged thick slough with serosanguineous discharge delimited by raised clear cut and slightly undermined margin and is commonly situated on the anterior aspects of lower legs of barefooted laboring people It is especially found during the months of July to December On microscopic examination the pus shows many gram negative fusiform bacilli and there also may be spirochetes and other microorganisms present Thus the disease is a distinct clinical and bacteriologic entity

The incubation period varies from 2 to 4 days

Site—The ulcer is commonly found below the knees that is on parts of the body most exposed to telluric contamination Lichtman (1947) found it on the anterior surface of legs in the middle or lower third in 41 4 per cent of the cases Occasionally the trunk elbows and fingers are affected and destruction of the nail bed may follow

Now the question arises as to why the lower legs and ankles are so commonly involved The answer to this is that the infection is derived from the soil and grasses that the legs are most liable to trauma particularly in the barefooted and that the adventitia of blood vessels of the lower third of the leg is very richly supplied with vasoconstrictor nonmedullated nerve fibers with the result that the amount of blood available to the tissues is reduced rendering the latter more prone to infection

larged and tender glands in only 4 per cent of his cases, and Apostolides (1922) in 10 per cent only It is only when there is a secondary infection with cocci and gram negative bacilli that glands are involved, and in such cases pyogenic organisms are found in the ulcers as well as in the glands The disease is, as a rule, nonfebrile except in very severe cases with pronounced secondary infection and complications Clements has recorded fever in the acutely phagedenic type in young children

COURSE AND PROGNOSIS

Prognosis is usually good Death is extremely rare though morbidity is high in some countries Most cases heal in 6 weeks to 3 months Average stay in the hospital before penicillin treatment was discovered was 141 days (Hughes 1931), though copper sulfate or "lock up" treatment considerably reduced the number of days On the other hand, Pinkerton (1947) from South Iran, writes that before the advent of penicillin type II acute phagedenic ulcer used to cause death unless amputation was performed

IMMUNITY

There is no immunity, either local or general A patient may get another fresh ulcer when old ulcers have completely healed Panja (1945) could reproduce fresh ulcers at the sites of healed ulcers Pandit (1945) recorded recurrence of ulcers within 1 year in 8 per cent of his cases Lichtman (1947) noted scars of previous ulcers on the backs of hands and forearms in 43 per cent of his cases

COMPLICATIONS

As a rule there are no complications and the disease is arrested at the deep fascia but sometimes bones and tendons are exposed Bharucha (1943) found osteoplastic periostitis in 13 cases out of 179 cases studied Formation of subperiosteal new bones or extensive osteoporosis was noted Shepherd (1946) observed osteomyelitis in some of her cases There is at times a serious danger to the life or limb of a patient At Uganda, 2 cases are on record a father had an ulcer which divided his tibia and the son was suffering from an ulcer extending from knee to ankle Both had to undergo lifesaving amputation Spontaneous fractures of tibia and fibula have been recorded Tetanus, erysipelas, lymphangitis, and phlebitis may occur but they are extremely rare

In a few cases, *Staphylococcus aureus* has been isolated by blood culture by some workers

DIAGNOSIS

The phagedenic phase of the disease commonly seen presents no difficulties in diagnosis The points for diagnosis are

1 Circular or oval ulcer with raised, clear cut, slightly undermined margin, cup shaped, full of copious, grayish yellow, blood tinged pus and slough with serosanguineous discharge, very tender to touch, and situated as a rule on the lower extremities, below the knees

Cavity—Cup shaped, full of grayish yellow, blood tinged, thick, often foul smelling pus and slough *Pus is sometimes so copious that several spoonfuls can be removed with a Volkmann s spoon* The pH of pus varies from 7 4 to 8 0

Floor—Formed by exquisitely tender bleeding granulation tissue The slough is adherent to the base The ulcer may exceptionally be deep enough to expose tendons muscles and even bones Lichtman (1947) records extension to tendons and bones in 34 per cent of his cases In the majority of cases the ulcerative process does not extend beyond the deep fascia

Evolution—Various stages of the ulcer have been described In the early stage there is either a bleb with seropurulent and sanguineous content or a blunt conical painful papule In 2 or 3 days the characteristic phagedenic or sloughing phase starts and by a process of coagulative necrosis pus and gangrenous slough are formed The ulcer spreads rapidly in 5 to 8 days and the patient feels difficulty in walking and sometimes has to be carried in

Fig 191—Naga sore showing typically raised margin.

arms A peculiar watery serosanguineous discharge with a putrid odor runs down from the ulcer Later after weeks or months the chronic indolent stage begins The edge of the ulcer becomes rolled and the base hard, slough is either absent or present to a slight degree fusiform bacilli are no longer found and pain is considerably diminished It is at this stage that considerable disagreement has occurred as to correct clinical bacteriologic and histologic diagnosis It may be that the so called tropical ulcers in Guatemala (Golden and Padilla 1946) are of this stage The authors have not found in ulcers of 2 weeks duration any exudate or fusiform bacilli

In the healing stage the ulcers are clean and practically painless Epithelization starts at the periphery Microscopic examination may show gram positive cocci only The healing is often slow and ends in a whitish scar

Neighboring glands as a rule are not enlarged Pattanayak (1944) and Albasi (1944) did not find any enlarged glands Clements (1936) found en

by each with his own form of treatment After prolonged suffering spontaneous cures have also been noted A careful dressing with simple normal saline alone cures many cases To assess the value of a particular form of treatment several factors such as the number of days for cure the state of health of the patient his diet whether the treatment is ambulatory or the patient is in a hospital and the stage of the ulcer—all should be taken into consideration

Hare (1946) has summarized the comparative value of several lines of treatment as follows

Bharucha (1943)—Dressing with copper sulfate solution 1 in 150 until all sloughs separate then dressing with 40 per cent codliver oil in petroleum jelly average healing time 35 to 54 days but dressing with sulfanilamide and iodoform powder each 50 per cent average healing time 20 to 36 days

Panja and Ghosh (1944)—Dressing with sulfanilamide dusting powder average healing time 21 to 42 days but sulfanilamide dusting powder locally in the early stage and copper sulfate in later stage average healing time 40 days

Rao et al (1945)—Sulfathiazole paste (sulfathiazole 12 calcium oleate 2 beeswax 3 codliver oil 60 water 40), average healing time 30 to 35 days

Marsh and Wilson (1945)—Occlusion by plaster of Paris after bipp and zipp * average healing time 31 to 39 days

Brecher (1946)—Occlusive treatment by adhesive plaster average healing time 42 days

Hare (1946)—Vitamin A by mouth and dressing with codliver oil average healing time 45 days but dressing with zipp average healing time 39 days

James (1932)—Excision and skin grafting average healing time less than 2 weeks very successful

Numerous drugs have been used by various workers

Bactericides Formalin iodine mercury iodoform electrolytic chlorine eusol

Spirocheticides arsenic bismuth antimony

Oxidizing agent potassium permanganate

Reducing agent pyrogallic acid

Caustics copper sulfate silver nitrate phenol

Dyes acriflavine Mercurochrome gentian violet

Astringents

Emollients

Hydrotherapy

A resume of the treatment by various workers is given

Vincent s Dusting Powder—Vincent (1945) dried the ulcer after cleaning with normal saline and then applied the dusting powder (calcium hypochlorite 1 part boric acid 9 parts) and renewed the dressing every 3 or 4 days He noticed healing in 2 or 3 weeks Corpus (1924) more than 26 years ago followed practically the same method He washed with a solution of potassium per

*Zipp — zinc oxide 1 iodoform 2 and liquid paraffin 2

2 Patients are often barefooted laborers usually from an generally poorly nourished

3 History of trauma or skin lesion frequently present

4 No constitutional symptoms as a rule

5 The criterion of diagnosis the presence of fusiform times of spirochetes

DIFFERENTIAL DIAGNOSIS

The following diseases come under consideration in differe

Veld sore (Septic sore desert sore Barcoo rot) is a punched-out ulcer usually multiple present on the back of t arms or legs and sometimes on the face mainly seen in Eur in the tropics The ulcer begins like the vesicle of an impetig colored fluid There is little undermining under the edge Str Staphylococcus only are usually found in the discharge

Cutaneous diphtheritic ulcer is a punched out deep ulcer per cent of cases with rolled edge and floor covered by adher seen usually in Europeans and located on their extremities

Corynebacterium diphtheriae can be isolated in the majori Faucial diphtheria occurs in some of the cases and diphtheria isolated from the nose and the throat Diphtheritic neuritis as a complication Antidiphtheritic serum 4 000 units subcut vicinity of the ulcer shows a strikingly beneficial effect

Diphtheritic ulcers of Chittagong hill tracts of India (Garig sore) are found on the lower extremities have rolled edges covered by membrane and little or no pus A virulent diphthe been isolated from every case and ulcers have been reproduced of the bacilli (Pasricha and Panja 1940) Antidiphtheritic value in such ulcers

Cutaneous leishmaniasis (Oriental sore Baghdad boil or seen on exposed parts of the body it starts with a hard papule later into an ulcer with ragged edges thick crust on the top a dish edema at the periphery *Leishmania tropica* is easily demo scrapings of the ulcer or at the edematous margin

Ecthyma is a superficial stubby ulcer with a hard edge an lowish crust and without any undermining Staphylococcus Streptococcus are found in the lesion sulfathiazole therapy s cific

Syphilitic gummatous ulcer yaws varicose ulcer, trophic u tuberculous ulcer, cancerous ulcer, sporotrichosis and **indole** various causes must sometimes be distinguished from the trop ulcer There are no fusiform bacilli in any of these lesions

TREATMENT

Papers have been published on this aspect of the disease m

Connell and Buchanan (1933) used with success zipp (zinc oxide 1 iodc form 2, and liquid paraffin 2) first and then applied plaster of Paris on th top Grindlay (1944) recommended dusting with a sulfonamide after me chanical cleaning, then application of zipp with a piece of lint and on th top plaster of Paris kept in position for 2 to 3 weeks After this period h found clean granulation tissue ready for skin grafting Connell (1944) als advocated exactly the same method Walker Taylor (1945) practiced curet tage or excision followed by occlusive dressing with plaster of Paris and h found the average number of days of hospital stay to be 28 2 in the first grou of cases and 17 8 in the next group Diniz (1945) also used plaster of Paris but called the method "Zeno process" which was recommended for burns b Professor Zeno in 1943 Hammond (1945) used with success the occlusiv dressing made up with plaster of Paris 3 tragacanth 1 and acriflavine 0 001 all ground in a mortar before application He called such a dressing "Almaz Patch" Marsh and Wilson (1945) advised their "lock up" method of treat ment by bipp followed by zipp and then encasing the lesion in plaster o Paris Out of 81 cases 59 healed in an average time of a little over 2 weeks Gill (1945), in Palestine practiced the ambulatory treatment with satisfac tory results by dusting first with sulfanilamide powder and then applying plaster of Paris The ulcers healed in 1 to 3 weeks Jarvis (1945) used zipp followed by plaster of Paris with apparently good results

Adhesive plasters were used by some workers in place of plaster of Paris Sayers (1932) reported excellent results with a 3 inch spiral bandage of ad hesive elastoplast changed every 3 to 4 days and later weekly Bell (1934) used strapping with adhesive zinc oxide plaster with gratifying results Nath (1946) recommended strapping with Leucoplast in place of plaster of Paris and noticed healing in 15 days whereas treatment with copper sulfate and sulfonamide resulted in healing in 35 days a much longer time than in the fixation method

Local Sulfonamide Therapy—Bayley (1939) reported good results with sulfanilamide applied externally Earle (1942) used sulfanilamide locally in early ulcers and found local application of whale oil extremely valuable in advanced ulcers Abbasi (1944) recorded "marvelous results" in his 11 cases with sulfanilamide dusting powder Mina (1945) painted the ulcers with 2 5 per cent tincture of iodine and then covered them with a dry powder con sisting of sulfanilamide 1 part and magnesium sulfate 1 part Healing took place in 8 to 14 days He deprecated the use of watery solutions of any anti septic Scovel (1946) used daily dressing with sulfonamides and zinc perox ide for 5 days followed by daily irrigation with warm normal saline under moist dressing for 8 days Finally, he practiced surgical method of treatment by pinch skin grafts Hare (1946) made a comparative study of the treat ment by sulfonamides copper sulfate magnesium sulfate, and codliver oil but finally decided on penicillin as the best In his large series of cases Grenoilleau (1946) used sulfanilamide dusting powder, he sprayed Sulfarsenol or Novoarsenobenzol solution every 2 to 3 days and achieved rapidly a good

manganate (1 4 000) and then dusted with Vincent s powder and found clean granulation tissue from the fourth to sixth day

Copper Sulfate—Treatment with local application of copper sulfate was first advocated by Annesley (1828) in the Burma expedition more than a century ago and later in 1922 by Mathur who reported that all the ulcers healed quickly when treated with copper sulfate lotion He went on to say that the drug appeared to be specific Still later, in 1925, the drug was used by Terdschanian in 10 per cent strength McGuire (1933) used the drug in the following formula copper sulfate *180 gr phenol pure 1 fluid drachm* distilled water 1 fluid ounce this formula was followed by a dusting powder composed of iodoform 1 part and bismuth subgallate 3 parts and was used for 2 years in about 2 000 cases in the Assam tea gardens McGuire found it extremely useful One objection to the use of this mixture is that phenol is not soluble in the small amount of water used and therefore it floats on the top of the water Later (1944) he followed James (1938) and replaced water by glycerin Gunther (1938) used the drug in a dilution of 1 150 as a wet dressing renewed it every 4 hours and continued in this way for 36 hours when all sloughs cleared up *He found the drug to be apparently specific James (1938) advocated the formula copper sulfate 240 gr phenol 1 fluid* drachm glycerin 1 fluid ounce The results were good Such an application according to Panja (1945) was too strong and caused much pain sometimes lasting for the whole night and disturbing sleep Earle (1940) used the drug successfully in the same strength as Gunther Panja and Ghosh (1944) employed the drug at the beginning to remove all sloughs and then recommended dusting with a sulfanilamide powder Panja (1945) advised repeated dressing at least 3 times a day by irrigation with plain boiled water or weak mercuric chloride solution to remove the anaerobic condition formed by the thick slough and under which the fusiform bacillus shelters and multiplies The irrigation was followed by painting with copper sulfate solution in glycerin (copper sulfate 120 gr phenol 1 fluid drachm glycerin 1 fluid ounce) and was then repeated soon after the pain so as to remove the excess of the caustic Finally to ensure anaerobiosis a thick absorbent pad soaked in a solution of potassium permanganate (1 5 000) was applied All pus and sloughs from even bad cases disappeared in 2 to 4 days When no pus was noticed for 3 to 4 consecutive days and when clean granulation was visible it was only then that the use of copper sulfate was discontinued and plain boric or scarlet red ointment was applied To test the real efficacy of a drug Panja waited for the result after applying a final dressing with a bland ointment and not with saline because a saline dressing alone repeatedly changed was found by him to cure several cases Smythe (1946) treated 627 cases by first washing and then painting with pure phenol instead of copper sulfate solution 6 times a day he found the result satisfactory

Occlusive Dressing—Occlusive dressing by plaster of Paris has been advocated by a number of workers Connell and Buchanan (1933) Grindlay (1944) Connell (1944) Walker Taylor (1945) Irvine (1945) Diniz (1945) Hammond (1945) Marsh and Wilson (1945) Gill (1945) and Jarvis (1945)

Connell and Buchanan (1933) used with success zipp (zinc oxide 1 iodoform 2 and liquid paraffin 2) first and then applied plaster of Paris on the top Grindlay (1944) recommended dusting with a sulfonamide after mechanical cleaning then application of zipp with a piece of lint and on the top plaster of Paris kept in position for 2 to 3 weeks After this period he found clean granulation tissue ready for skin grafting Connell (1944) also advocated exactly the same method Walker Taylor (1945) practiced curettage or excision followed by occlusive dressing with plaster of Paris and he found the average number of days of hospital stay to be 28 2 in the first group of cases and 17 8 in the next group Diniz (1945) also used plaster of Paris but called the method Zeno process ' which was recommended for burns by Professor Zeno in 1943 Hammond (1945) used with success the occlusive dressing made up with plaster of Paris 3 tragacanth 1 and acriflavine 0 001 all ground in a mortar before application He called such a dressing Almazi Patch Marsh and Wilson (1945) advised their lock up ' method of treatment by bipp followed by zipp and then encasing the lesion in plaster of Paris Out of 85 cases 59 healed in an average time of a little over 2 weeks Gill (1945) in Palestine practiced the ambulatory treatment with satisfactory results by dusting first with sulfanilamide powder and then applying plaster of Paris The ulcers healed in 1 to 3 weeks Jarvis (1945) used zipp followed by plaster of Paris with apparently good results

Adhesive plasters were used by some workers in place of plaster of Paris Sayers (1932) reported excellent results with a 3 inch spiral bandage of adhesive elastoplast changed every 3 to 4 days and later weekly Bell (1934) used strapping with adhesive zinc oxide plaster with gratifying results Nath (1946) recommended strapping with Leucoplast in place of plaster of Paris and noticed healing in 15 days whereas treatment with copper sulfate and sulfonamide resulted in healing in 35 days a much longer time than in the fixation method

Local Sulfonamide Therapy—Bayley (1939) reported good results with sulfanilamide applied externally Earle (1942) used sulfanilamide locally in early ulcers and found local application of whale oil extremely valuable in advanced ulcers Albasi (1944) recorded ' marvelous results" in his 11 cases with sulfanilamide dusting powder Mina (1945) painted the ulcers with 2 5 per cent tincture of iodine and then covered them with a dry powder consisting of sulfanilamide 1 part and magnesium sulfate 1 part Healing took place in 8 to 14 days He deprecated the use of watery solutions of any antiseptic Scovel (1946) used daily dressing with sulfonamides and zinc peroxide for 5 days followed by daily irrigation with warm normal saline under moist dressing for 8 days Finally he practiced surgical method of treatment by pinch skin grafts Hare (1946) made a comparative study of the treatment by sulfonamides copper sulfate magnesium sulfate and codliver oil but finally decided on penicillin as the best In his large series of cases Grenoilleau (1946) used sulfanilamide dusting powder he sprayed Sulfarsenol or Novoarsenobenzol solution every 2 to 3 days and achieved rapidly a good

effect Smythe (1946), on the other hand found sulfonamides or iodoform of little value in the active stage of the disease

Iodoform—Kerby (1932) obtained best results by curettage followed by application of bipp McGuire (1933) used iodoform as a dusting powder mixed with bismuth subgallate following the treatment with copper sulfate Hoffman's (1941) zisp (zinc peroxide iodoform sulfanilamide and liquid paraffin) has also been used with success Costa (1944) cleaned the ulcers with a solution of potassium permanganate (1 8 000) and then applied 15 per cent iodoform in ether

Operative Treatment—James (1932) practiced excision and immediate skin grafting under spinal anesthesia He noted complete success in 41 out of 45 cases Healing took place in an average period of 13 days Kerby (1932) also advocated preliminary curettage to obtain the best results Skin grafting has been recommended by many workers when the ulcers are found clean and granulating

Miscellaneous—Hayman (1914) tried x ray exposure and obtained disappearance of all pain in the first few days and rapid cure by cicatrization but Clements (1936) discredits this result Corpus (1924) used 3 per cent solution of arsphenamine locally in 598 cases in the Philippines and cured 410 cases He declared the treatment most effective " James (1925) applied wet dressing with 25 per cent solution of magnesium sulfate and found it ' uniformly successful " Hughes (1931) used quinine or cinchona as a dusting powder and found very good results ' Innes (1931) like Hughes used quinine externally and recorded the results as magical Brown (1935) found magnesium sulfate as the most suitable dressing Mohiuddin (1943) used a wet dressing with Novoarsenobenzol 0 3 Gm in 1 ounce of distilled water with satisfactory result Pampana (1923) obtained excellent results with daily dressing of acriflavine solution (1 1 000) Shircore (1944) irrigated the ulcers with potassium permanganate (1 4 000) dusted with his A K powder (acriflavine 3 5 gr water ½ pint and kaolin ½ pound) and then covered with a piece of lint wrung out in sterilized almond oil every other day He found highly gratifying results Amaral in Brazil found local application of normal dried serum exceedingly successful

Summarizing all the above lines of external treatment that have been advocated and practiced in the old days the following four methods appear to be most successful (1) frequent cleansing with potassium permanganate solution (1 5 000) and dressing with normal saline (2) application of copper sulfate phenol glycerin, (3) occlusive dressing with plaster of Paris or elastoplast and (d) excision and immediate skin grafting in suitable cases

Internal Treatment

Scott (1917) found antimony parenterally useful Mei (1920) used tartar emetic intravenously and externally as a dusting powder with apparently good results Crichlow (1920) found Galyl injection ' wonderfully effective " Apostolides (1922) recorded best results with intravenous Novoarsenobenzol Abraham (1923) found good results with his new treatment namely hot

dressing with calx chlorinata and 2 per cent antimony tartrate intravenously Loewenthal (1932) gave daily intravenous injection of 15 gr of calcium chloride dissolved in 10 c c of distilled water and found rapid separation of *slough and healing* But his cure rate was 52 per cent only There was no improvement in about 12 per cent of his cases and 4 4 per cent of the patients died Brown (1935) found calcium chloride 15 to 30 gr intravenously daily definitely beneficial and also parathyroid by mouth which promoted rapid epithelization Berry (1943) used intravenous tartar emetic 1 to 10 c c of 1 per cent solution *in Indo China he reported good results Ulcers took* 6 to 8 days to heal Tournier recorded a single subcutaneous injection of 0 30 Gm of Novoarsenobenzol dissolved in 4 per cent sodium chloride most satis factory Houssiau gave intramuscular injection of bismuth on 3 successive days he also applied bismuth hydroxide externally and obtained complete healing in a case Pons found that a course of 4 to 5 injections only of anti spirillary vaccine exerted a rapid action on the ulcers and he noted cessation of all pains in 48 hours and cicatrization after the fourth day On the other hand *Panja (1945) obtained no good results with a vaccine made from cul* tures of fusiform bacilli

Conclusion

Regarding the internal treatment and general management most work ers are of the opinion that calcium arsenic antimony sulfonamides non specific vaccines or even vaccines made from a culture of fusiform bacillus and vitamin feeding are generally of no value No rapid healing or healing at all is obtained by these medicaments Rest is certainly important A deeply ulcerated locomotive organ is not expected to do well if it is burdened with gravitational stasis and at the same time allowed to continue its work *Athough ambulatory treatment may cure all cases still if rest be enforced* cure is certainly hastened If a patient is poorly nourished and debilitated or suffering from diseases such as malaria dysentery etc good feeding and treatment of his associated ailments will promote more rapid healing

PENICILLIN

Recently penicillin has been spoken of highly and declared to be the drug of choice *or apparently specific by several workers starting from Hamm* and Ouary (1944) and Panja (1945) working independently in America and India respectively down to Moreau and Ouary (1945) Blank (1947) Webb (1946) Hare (1946) Whitestone (1947) Pinkerton (1947) and Gutch (1947) Panja while working on the sores in Calcutta in 1943 had sufficient experimental and circumstantial grounds to formulate no fusiform no Naga sore and know ing that *penicillin was effective in fusospirochetal affections* he thought of trying the drug in tropical ulcer unfortunately no penicillin was then avail able to the civil population in India He had to write to Fleming for supply of a culture of *Penicillium notatum* and to prepare crude penicillin in Czapek Dox medium in his laboratory But when his crude penicillin was ready he received a supply of penicillin (Lilly) which he used externally as a dressing

effect Smythe (1946), on the other hand, found sulfonamides or iodoform of little value in the active stage of the disease

Iodoform—Kerby (1932) obtained best results by curettage, followed by application of bipp McGuire (1933) used iodoform as a dusting powder mixed with bismuth subgallate, following the treatment with copper sulfate. Hoffman's (1941) zisp (zinc peroxide, iodoform, sulfanilamide, and liquid paraffin) has also been used with success Costa (1944) cleaned the ulcers with a solution of potassium permanganate (1 8 000) and then applied 15 per cent iodoform in ether

Operative Treatment—James (1932) practiced excision and immediate skin grafting under spinal anesthesia He noted complete success in 41 out of 45 cases Healing took place in an average period of 13 days Kerby (1932) also advocated preliminary curettage to obtain the best results Skin grafting has been recommended by many workers when the ulcers are found clean and granulating

Miscellaneous—Hayman (1914) tried x ray exposure and obtained disappearance of all pain in the first few days, and rapid cure by cicatrization, but Clements (1936) discredits this result Corpus (1924) used 3 per cent solution of arsphenamine locally in 598 cases in the Philippines, and cured 410 cases He declared the treatment "most effective" James (1925) applied wet dressing with 25 per cent solution of magnesium sulfate and found it "uniformly successful" Hughes (1931) used quinine or cinchona as a dusting powder and found "very good results" Innes (1931), like Hughes, used quinine externally and recorded the results as "magical" Brown (1935) found magnesium sulfate as the most suitable dressing Mohiuddin (1943) used a wet dressing with Novoarsenobenzol, 0 3 Gm in 1 ounce of distilled water, with satisfactory result Pampana (1923) obtained excellent results with daily dressing of acriflavine solution (1 1,000) Shircore (1944) irrigated the ulcers with potassium permanganate (1 4,000), dusted with his A K powder (acriflavine 3 5 gr, water ½ pint, and kaolin ½ pound), and then covered with a piece of lint wrung out in sterilized almond oil every other day He found highly gratifying results Amaral, in Brazil, found local application of normal dried serum exceedingly successful

Summarizing all the above lines of external treatment that have been advocated and practiced in the old days, the following four methods appear to be most successful (1) frequent cleansing with potassium permanganate solution (1 5,000) and dressing with normal saline, (2) application of copper sulfate- phenol glycerin, (3) occlusive dressing with plaster of Paris or elastoplast, and (4) excision and immediate skin grafting in suitable cases

Internal Treatment

Scott (1917) found antimony parenterally useful Mei (1920) used tartar emetic intravenously and externally as a dusting powder with apparently good results Crichlow (1920) found Galyl injection "wonderfully effective" Apostolides (1922) recorded best results with intravenous Novoarsenobenzol Abraham (1923) found good results with his new treatment, namely, hot

by using this method it may not be possible to have a clean base at one sitting After washing the ulcer all fluids should be mopped up with a piece of absorbent cotton wool and then a sterile pad of gauze or absorbent cotton soaked in penicillin solution 500 to 1 000 units per c c should be applied On the top of this should be put oil silk and nonabsorbent cotton and bandage The ulcer should be dressed in this way twice a day An intramuscular injection of 20 000 units of penicillin should also be given and repeated every 3 hours if the ulcer is of severe type As a rule repeated dressing with penicillin alone suffices and injections are not required When no pus is seen for 3 consecutive days a boric ointment with shark or codliver oil (2 fluid drachms to an ounce) or scarlet red ointment should be applied If there is delay in healing skin grafting by the pinch method should be practiced General condition of the patient and associated ailments should also be looked after at the same time to promote faster healing

PROPHYLAXIS

As an injury is the starting point in most cases the wearing of puttees has been advised and incidence of the disease found enormously decreased (Roy 1928) Such a practice is not always possible Cleaning of the lower legs after a day s work is very important and whenever there is any injury or impetigo or boil or bite penicillin ointment should be applied if possible If this is not available the parts should be painted with tincture of iodine followed by tincture of benzoin compound or a boric ointment may be applied Grenoilleau (1946) has advised the use of tincture of Mercurochrome and immediate bandaging In fact every precaution should be taken to prevent any skin lesion from turning into the tropical ulcer A daily routine inspection of the legs of all laborers before joining the day s work should be carried on during an epidemic season Such a procedure is sure to curtail the incidence to a very large extent Destruction of flies has been advised but this does not appear to be essential nor is it a practical proposal

in 1 available case only in 1944 as the epidemic had then largely subsided Judging from his experiences in treating a large number of cases by various methods of treatment he was impressed with the dramatic result in 1 case alone So a note was sent in 1944 to the *Indian Medical Gazette* without any knowledge that in the same year (1944) Hamm and Ouary had found penicillin effective in 18 cases They used the drug locally in a strength of 2 800 units per c c and they found all sloughs and pain disappearing within a few days and complete healing taking place in 3 to 4 weeks Moreau and Ouary later (1945) used penicillin 250 units per c c in 19 cases as a local dressing with success Blank (1947) recorded in detail with photographs the successful use of *penicillin parenterally 20 000 units intramuscularly* every 3 hours covering 18 doses for about $2\frac{1}{4}$ days on only 1 bad case and remarked that the penicillin treatment was the treatment of choice Webb (1946) used the drug 500 units per c c as a local dressing twice a day and at the same time gave a maximum number of 6 intramuscular injections 15 000 units at a time at intervals of 3 hours Ulcers became clean in 1 to 3 days Hare (1946) practiced the combined method that is locally 500 units per c c for about 5 days and 15 000 units intramuscularly in 12 hours When the ulcers cleaned up a scarlet red ointment was applied Complete healing took place in a little over 3 weeks whereas in cases of ulcers treated by methods other than penicillin complete healing took place in more than 4 weeks Whitestone (1947) treated cases in the hospital with a local dressing of the drug 500 units per c c in most cases and also parenterally once a day but in bad cases only Average stay in the hospital was 23 1 days with the penicillin treated cases and 34 2 days in the control group of cases Pinkerton (1947) in South Iran used 2 000 units every 4 hours for 5 days and found the drug to exert a specific and rapid action He remarked also that the disease of type II that is the acute phagedenic type used to cause death before the advent of penicillin unless timely amputation was performed Gutch (1947) sprinkled dry penicillin powder over the surface of ulcers and then covered with petroleum jelly gauze In 32 cases out of 35 so treated healthy granulation tissue appeared in 1 to 3 days and he could apply pinch graft on the tenth day

From all these reports it is evident that penicillin promises to be the drug of choice for successful treatment of a disease which has hitherto incapacitated so many people in the tropical and subtropical countries of the world The advantages of penicillin treatment are that the treatment can be ambulatory there is no local or systemic reaction pain is relieved in 24 hours and quick healing takes place The treatment is also very simple and can be carried out by the patient himself

The treatment of tropical phagedenic ulcer may thus be summarized If the patient can be admitted to a hospital well and good If not he can have ambulatory treatment The ulcer should be washed thoroughly by means of a douche jet with plain boiled water or with potassium permanganate solution (1 5 000) and while the douche jet is playing on the ulcer, all adherent slough should be disengaged with a sterile cotton swab It is not usually possible to remove all the sloughs if an irrigator and a cotton swab are not used Even

tion Also, according to Snijders, bacteriophage may be present, even in young cultures these inhibit the growth and isolation of the Klebsiella At any rate, these very rare negative results do not invalidate the thesis that this microorganism is the cause of the disease

Apart from patients, *K rhinoscleromatis* is found in a small number of persons without clinical symptoms of scleroma, living in close contact with the patients, very probably these persons must be considered as carriers of the bacterium, especially those in whom the complement fixation test has been found to be negative

The bacterium has never been found outside the foci of scleroma This also adds to the probability that von Frisch's Klebsiella is indeed the causal agent of this disease

Some authors still doubt the etiologic role of the Klebsiella Ash and Spitz (1945) and Reyes (1946), who think it probable that the disease is caused by a virus, the Klebsiella growing symbiotically in the pathologic tissue The peculiar geographical distribution of *K rhinoscleromatis*—namely, only in certain localities where scleroma occurs, and there only in patients and in some of their immediate contacts—speaks against this hypothesis

The third postulate of Koch, the empirical production of the disease by inoculation of the Klebsiella, is the only one which has not yet been realized Although this must leave some uncertainty as to the etiology of the disease, very little doubt can exist that the bacterium of von Frisch is, indeed, the causative agent of the disease The same situation exists in leprosy, in that disease the significance of Hansen's bacterium is generally accepted

EXPERIMENTAL PRODUCTION OF SCLEROMA

De Simoni (cited by Hajek) tried to produce scleroma in man by injecting an emulsion of Klebsiellae into the nasal mucosa of a cachetic tuberculous patient, without success Rona (1899) injected the bacteria into the ear lobe of a patient with nasal scleroma but here also no result was seen in the course of five months Schlotter (cited by Hajek) implanted fresh scleromatous tissue under the skin of his arm, again without result

Many authors have tried to produce scleroma by inoculating animals with *K rhinoscleromatis* Many times granulomata have actually been produced after injection of the bacteria into the skin or the eye of mice, guinea pigs rats and rabbits These lesions showed the characteristic pathologic picture of the scleroma and from these granulomata the Klebsiella could be recovered (Sercer, 1932) It is doubtful, however, whether these lesions can be considered truly scleromatous The lesion produced is a disease of very short duration The granuloma appears after 8 or 10 days, and disappears after a few weeks, so that the very important characteristic of scleroma, the chronicity, is absent

EPIDEMIOLOGY

Since scleroma was first diagnosed by Hebra, knowledge about this disease has steadily increased and with increasing knowledge more and more cases have been discovered In Russia, for instance, only 21 cases were registered in 1888, in 1911, 128 cases, and in 1932, no less than 1,400 The disease has also been described for many years in other countries

The principal focus of the disease is in *eastern Europe* the Ukraine (along the Pripyat River), White Russia, and Poland More than 75 per cent of all cases observed have originated from these countries From this large focus it spreads toward the north

CHAPTER 34

RESPIRATORY SCLEROMA (RHINOSCLEROMA)

WILLEM KOUWENAAR

Rhinoscleroma is an infectious disease of the respiratory tract, with formation of granulomatous tissue with characteristic pathologic structure, occurring from the nose to the bronchi, and caused very probably by infection with *Klebsiella rhinoscleromatis* von Frisch

It was first described by Hebra (Vienna) in 1870 in eastern Europe, and has since been found in many other countries

In the majority of the endemic foci the malformation of the nose is not the principal or clinically most important localization of the scleromatous process, in many cases this organ is not involved in the process at all It is, therefore, advisable to change the old name, rhinoscleroma, given by Hebra, and to speak of the disease as "scleroma respiratorium" or "respiratory scleroma"

ETIOLOGY

Although experimental reproduction of the disease by inoculation with *K rhinoscleromatis* has not as yet been successful, sufficient proof exists that this microorganism is indeed the cause of the disease

This bacterium, first isolated and described by von Frisch in 1882, belongs to the group of gram negative encapsulated bacteria It grows well on common media, so that it can be easily cultivated It is closely related to other capsulated bacteria, *K ozenae* and *K pneumoniae*, but cultural differences exist, and although the capsular antigens of the three species are affiliated, all examined strains of *K rhinoscleromatis* have in common a specific body antigen Thus this bacterium can be differentiated clearly from the other Klebsiellae

The *K rhinoscleromatis* proved to be a sharply defined species, strictly uniform, culturally as well as antigenically, the capsules being constantly of the "C" type The strains obtained with the necessary precautions from the patients with scleroma belonged without exception to this species and *K rhinoscleromatis* was found only in patients and their immediate contacts, and never in regions free from scleroma There exist, however, strains of *K ozenae* the body antigen of which shows close relationship to that of *K rhinoscleromatis* (Wielenga, 1937)

the scleromatous tissue and not from the surface of the mucosa With this precaution, pure cultures are as a rule obtained In slides made from the tissue, the bacterium can be found in cells which are highly characteristic of the pathologic picture of the disease, the cells of Mikulicz, and between the cells, often in a group The Klebsiellae can be cultivated in a large majority of the cases They have not been found in all patients, but negative results can be explained by the fact that material was taken from an unfavorable place, or that the bacteria disappeared as a result of local cicatrization and cessation of the process of inflamma

counteract the spread of scleroma among the population of this island. Finally in Flores, 5 cases were seen by Haulussy and Sardjito (1939)

Up to 1940, some 150 to 200 cases were found in Indonesia, so that *this archipelago* may be rightly considered as one of the major endemic centers Recalling that in most of the places systematic examination of the often backward population has not yet been carried out efficiently, the real number of infected persons may be much higher

Shawket al Zahawi saw a patient with scleroma in Iraq Some cases have also been described in Palestine, possibly imported from Russia

Possibly 1 case in a Frenchman originated in the Philippines (Argaud and Laval, 1925), however, the patient had left the islands 25 years before the disease was discovered. Crawford and Gerundo (1947) described 2 cases from Hawaii

In Central America scleroma respiratorium has been described from many countries

San Salvador Alvarez (1885), 30 cases (cited by de Moor, 1929), Reyes (1946), 200 cases

Guatemala Castellani (1926), 6 cases

Costa Rica Pena Chavarria and Nauck (1929), *5 cases in 4 years*, Rotter and Peña Chavarria (1933), 4 patients, 1 with a secondary growth in the colon, Muhlens (1927), several cases

Colombia Findler (cited by de Moor), 1 case, Peña Chavarria and Nauck (1929), according to whom the disease is located in the cooler climate of the hills

Cuba Castello Dominguez (1923), 1 case, Gonzalez (cited by Wielenga), 1 case

Martinique Vildrain (cited by Belinoff), 2 unconfirmed cases

Mexico Pietro (cited by de Moor), 1 case, Alderson (1914), 1 patient, Lewis (cited by Belinoff), 2 cases

In *Africa* the disease occurs principally in the northern part of the continent In *Egypt*, a major focus exists, as described by Cole Mallon (1929) and Shaheen Hassan Bey (cited by Wielenga), according to whom about 20 patients with scleroma are observed annually in the Cairo hospitals Some cases are described from *Morocco, Algeria,* and *Tunisia (Brault et al, cited by Argaud, Dekester and Martin, 1923, Decrop et al, 1925,* cited by de Moor, Berge 1942) In Central Africa 1 case was reported by Fischer (1932) near *Lake Victoria*, Worms (cited by Belinoff) saw 3 unconfirmed cases in *Togo*

Altogether, about 3,000 to 4,000 cases are known in the entire world, but no doubt more cases will be found The disease is by no means just a curiosity, on the contrary, it is of sufficient importance to justify more extensive examination of the population of many of the aforementioned countries as well as the surrounding districts Apart from the clinical observation bacteriologic, serologic and pathologic examination are necessary to guarantee reliable results

The distribution of scleroma respiratorium in circumscribed foci suggests *that it is a contagious disease, this hypothesis* also best explains the other epidemiologic features

Scleroma is a disease that principally attacks the poorer population According to Belinoff's vast statistics (1932), 94 5 per cent of the known cases in eastern Europe are poor laborers and peasants *The same is true of most* of the cases in the tropics Bad housing, insufficient food according to some authors (Lewis cited by Belinoff) even nutritional imbalance, and often very primitive living conditions (sleeping closely together in badly ventilated houses may be of great importance) are present in all major foci *It is es*sentially a disease of the "great unwashed" Long existing, prolonged contact in an unhygienic environment, among people of primitive hygienic hab

(Estonia, Latvia, former East Prussia), the east (Russia), the south (Yugoslavia, Hungary), Romania), and the west (Czechoslovakia, Germany) It is chiefly a disease of the Slavs, possibly they introduced it in other countries by immigration

In other European countries small foci are described, often including only a few cases *The largest foci, probably related, are found in southern Switzerland (canton of Valais) and Italy* (from the north, where most of the cases occur, to Naples and even Catania) It is possible that this focus also originates in emigration from eastern Europe Isolated cases have been described from Sweden, Denmark, and France, very probably imported

Some patients are reported in *Siberia* and *Turkestan*, most of them having migrated from Russia One case was seen in the Hopeh province in *China*

In the *United States*, several cases have been reported, the large majority imported from eastern Europe But apart from these, a number of cases have been seen in persons born in the United States and who had never left the country In statistics from the American Subcommittee on Rhinoscleroma, published by Belinoff (1932), of 37 cases registered, 26 certainly were Russians, Poles, etc, and 11 were born in North America—cases are mentioned from North Carolina and Cincinnati, Ohio (Alloway), New York (Tarell), Michigan (Howland), Greenville (Jervay), and Arkansas (Moore) Probably autochthonous cases were also described by Wende (1896, cited by de Moor), Stelwagon (1913), Watkins (1921, a Negro from Maryland, who for short times had been in South America), Kernan (1924), Canfield (cited by Wielenga, a case from Michigan, the parents had emigrated from Poland), Wood (1925, cited by Wielenga, the parents were immigrants from Austria), Figi and Thompson (1928, from New Jersey), Simpson and Ellis (1939, a patient from South Carolina), and perhaps a few others According to Cunning and Du Pont (1943), 102 cases have been reported from the United States and Canada, including 16 in native born subjects Very little is known about the contact of those patients with immigrants from a focus of scleroma in Europe or Central and South America The significance of scleroma respiratorium for the United States seems not yet clearly established

In South America, cases have been reported from *Brazil* (Florence, 1909—1 patient, Duarte, 1923—2 cases, Terra cited by de Moor—8 Negroes, Falçao, 1945, who states that 26 cases have been reported since 1890, 16 of them autochthonous), and especially from *Chile*, where del Rio (1909, cited by de Moor) saw 31 cases Scleroma has also been reported from *Argentina* (Bilina and Aberastury, 1933, who saw 5 patients from the Andes 4 born in Argentina, these cases are perhaps related to the focus in Chile) Vidal (1891, cited by Argand and Laval saw the disease in *Peru*

Endemic foci of scleroma likewise exist in *tropical countries*

In *Asia*, a relatively large number of cases have been reported from India and Indonesia In *India*, the disease is widely scattered over the northern and central parts of the country, Keegan (cited by Snijders, 1931) saw 11 cases from the Central Provinces, Castellani and Chalmers mention one case from Ceylon Acton (cited by Snijders, 1931) saw several cases from the Punjab, Nepal, Bengal, Bihar, Orissa, and the Central Provinces, Rao and Menon (1941) described 6 patients in Vizagapatam (Orissa), Mohanty (1945) one case in Orissa, Ghosh and Panja (1945) a case in Calcutta It appears that some concentration of the cases occurs on and around the Chota Nagpur plateau

In the *Indonesian archipelago*, a major focus exists After Snijders and Stoll (1921) had discovered the first patient in 1918, altogether about 90 cases were found among the Batak population in northern Sumatra (Kouwenaar et al, 1934) In southern Sumatra a focus exists in the Pasoemah district (Kuilman et al, 1937. 10 cases) In Bali, 13 patients were described by Noosten et al (1934), later 29 more cases were discovered In northern *Celebes*, scleroma is also rather frequent, Leimena and Sardito (1936) and Oomen and Kirschner (1938) found at least 15 patients suffering from the disease In *Java* several patients with scleroma were described (Djochana et al, 1934, Kuilman, 1938 a Chinese with symptoms of nose, pharynx, and larynx, Maasland, 1935, Ramali, 1936, and others) Here the cases are disseminated over the central and eastern parts of the island, and no definite focus could be found, although possibly a concentration *occurs in southeastern* Java, where more primitive conditions still prevail, Islam with its ritual ablutions will

why the disease, endemic among the Bataks of north Sumatra, never attacked the surrounding populations as the people are Mohammedans and consequently live as a rule in better conditions of cleanliness No racial immunity exists isolated cases may occur in other people but the way of living seems to be the principal factor

Probably this also explains the fact that in most of the endemic areas outside eastern Europe only small foci are found, between which no close contact exists These foci may be the remnants of a larger and more general endemic

The epidemiologic distribution *of scleroma in eastern Europe can be explained by* direct contact The connection between the scattered foci in the tropics is more difficult to understand The situation existing in Indonesia makes a hypothesis possible

At the present time a direct connection between the different Indonesian foci does not exist, but in every major focus (except possibly north Celebes) the principal inhabitants are descended from archaic strata of the population, who many centuries ago migrated in large numbers from India and are still anthropologically and ethnologically related (a common megalithic culture is found in these countries) to the Munda races from India (Chota Nagpur), among whom scleroma also occurs Possibly, as Snijders (1931) suggests, the disease was introduced in Indonesia with these migrating peoples in the remote past and has since survived among the descendants of these immigrants who still adhere to many of their archaic and primitive customs In this way, a relationship between the foci in north and south Sumatra Java, Bali, and Flores can be established

All arguments point to the belief that scleroma respiratorium is an old disease, slowly disappearing with the advent of better hygienic living conditions That the medical history of scleroma is only about 80 years old an argument used by Streit (193-) for his hypothesis that scleroma is a recent disease, can be explained by the scanty medical supervision in these usually backward countries, and by the supposition that the diagnosis formerly was faulty, just as today the uninformed make a diagnosis of leprosy, frambesia lupus or lues in classical cases of scleroma

PATHOLOGY

The scleromatous process consists principally of a massive and dense infiltration of plasma cells with some leucocytes and lymphocytes In the early stage of development many engorged blood vessels are present In the slides stained with hematoxylin eosin, many round red bodies are seen between the cells They occur sometimes in a cell with a still recognizable nucleus, sometimes the nuclei are separated after degeneration of the rest of the cell and form the bodies of Russell or Pellizari These are not specific but are found in many plasmocytic infiltrations Scattered through the infiltration single or in clusters, occur large cells with a frothy aspect usually consisting only of a small pyknotic nucleus narrow strands of cytoplasm and a membrane so that at first sight these cells give the impression of empty *holes in the preparation The cells do not contain fat* These are the cells of Mikulicz and are highly characteristic for the scleromatous process Their origin is uncertain

Except in the most recently developed parts of the granuloma *fibroblasts* may be seen, many bands of collagen connective tissue are spread through the lesion and often a hyaline mass is seen in the large parts of plasmocytic infiltration This explains the characteristic cartilaginous consistency of the scleromatous granuloma Later the connective tissue increases and in old lesions it forms the greater part of the granuloma which becomes smaller in this final stage of retraction and cicatrization

its, seems to be necessary for successful infection In this and other aspects the epidemiology of scleroma closely resembles that of leprosy These circumstances will cause repeated infestation over a long time which seems to be necessary for development of the disease perhaps by eventually creating a hypersensitivity to the bacterium probably also the infecting organism may become more virulent by frequent transference (as in the case of the meningococcus)

Burack believes that the geologic condition of the soil especially humidity, is of importance too Knowledge of any possible secondary factors which enable the bacterium to invade and to thrive in the human tissue is still lacking

Infection appears to occur directly from man to man It probably takes place by inhalation of droplets from a coughing or sneezing patient or possibly by direct contact

In the described conditions nasal infection in general is very frequent in a focus of scleroma This was shown by Wolff (1934) who examined the nasal flora of a large number of otherwise healthy Bataks (the population group in northern Sumatra) with endemic scleroma and compared the results with examinations of other Indonesians most of them living in the same country

The very frequent occurrence of fecal bacteria in the nose also observed by others (it is the general experience that cultivation of *K rhinoscleromatis* from the nasal mucosa is often made impossible by growth of quickly spreading Protei on the culture media) points to extremely defective hygienic conditions Frequent introduction into the nose of the scleroma bacterium in an infected vehicle seems plausible

Perhaps the observation of many authors (Streit 1932 Elbert et al 1927) that cases of *ozena* are also frequently seen in countries where scleroma is endemic has some importance to the possibility of invasion of the *K rhinoscleromatis* in the nose The significance of atrophy of the nasal mucosa has been discussed in the section on clinical symptoms

The appearance of multiple cases of scleroma in one family is quite common and is further proof of the contagiosity of the disease

Apparently the disease has had many new victims in the last 50 years in Russia Ukraine, Poland etc although better medical supervision of the exposed population better knowledge of the disease and its diagnostic possibilities (bacteriology complement fixation test pathology) and also the development of modern surgical methods may explain a considerable part of the numerical increase in registered cases In addition World War I (1914 1918) resulted in the introduction of scleroma in places where the disease had formerly been unknown But in many countries scleroma is disappearing In Switzerland, it is diminishing in frequency rather quickly apparently through the hygienic education and improvement in sanitary conditions reaching the formerly primitive human settlements in the remote valley (Barraud 1923) In Austria scleroma has almost completely disappeared

It can thus be understood that scleroma has never been able to take root in the more civilized countries of western Europe and North America This likewise explains

Fig 199—Rhinoscleroma. Extensive infiltration of nose and upper lip.

Fig 200—Rhinoscleroma. Hebra's nose.

The epithelium is often hyperplastic with desquamation sometimes atrophic In the mucous membranes metaplasia may be observed Scanty numbers of bacteria may be present

Malignant degeneration (carcinoma or sarcoma) is very rarely seen (Szmurlo 1932)

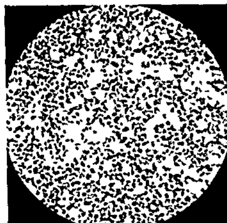

Fig 192 Fig 193

Fig 192 —Plasmocytic infiltration with many Mikulicz cells (×250) (Courtesy of E P Snijders)
Fig 193 —Mikulicz cells (×1500) (Courtesy of E P Snijders)

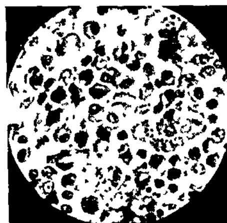

Fig 194 Fig 195

Fig 194 —Russell cells Mikulicz cells with Klebsiellae (Courtesy of E P Snijders)
Fig 195 —Capsulated bacteria in Mikulicz cells (×1500) (Courtesy of E P Snijders)

When special methods of staining (Heidenhain's hematoxylin Levaditi's silver impregnation) are applied many capsulated bacteria may be found in the Mikulicz cells and also in the interstitial spaces the *K rhinoscleromatis* In the interstice they may form large masses resembling colonies

nose often growing through the lip with formation of granulomata at the inner side The infiltration usually stops at the red margin of the lip

3 When perforation in the alveolar process of the *maxilla* occurs the teeth are loosened and expressed Growth through the hard *palate* is often seen seldom with an open perforation Small papules may develop on the gingiva The mucosa of the cheek is rarely attacked

4 The *pharynx* is often involved with formation of infiltration in the soft palate the tonsils and also other parts of the pharynx The pharyngeal are may be infiltrated and later retracted forming a sharp upper angle Deglutition is usually only very slightly impaired Synechiae between uvula and pharynx often occur The infiltration can attack the choanae the aperture becoming narrowed and sometimes completely closed Also the fornix of the pharynx can take part in the process When the opening of the Eustachian tube is surrounded by the inflammation narrowing and occlusion of the tube may follow many patients complain of buzzing in the ears and moderate deafness Very seldom the growth invades the inner ear even perforation through the ear and protrusion from the external auditory meatus has been reported In very severe cases the whole nasopharynx is closed and separated from the oral pharynx

5 Growth occurs also along the *lacrimal duct* with formation of a granuloma in the inner corner of the eye and in the lacrimal sac Sometimes a fistula of the duct exists The infiltration may proceed through the orbital fissure into the orbit with formation of exophthalmus

6 Very seldom infiltrations are found in the *tongue* sometimes as native granulomata sometimes infiltrating from the pharynx into the basis of the tongue

7 Scleroma of the *larynx* is very frequent in many countries Characteristic is the formation of subglottic infiltrations appearing as a third pair of vocal cords sometimes as a separate wedge at times attached to the cord As a result the voice becomes hoarse and later aphonic Separate infiltrations develop in the vocal cords themselves or in the wall of the larynx The granulomata may be covered with slime and crusts Stenosis may develop concentric or as a slit and suffocation is a real danger Sometimes infiltrations develop in the region of the aryepiglottic cartilage with malformation and retraction of the epiglottis Edema of the glottis and laryngeal perichondritis may develop In the larynx the atrophic form of scleroma has likewise been described often conjointly with hypertrophic processes

8 The *trachea* can be attacked according to Burack (1932) in a much larger percentage than appears from the literature The disease develops by spreading from the larynx or as primary granulomata Again circular stenosis may develop or synechiae may be found with formation of strings or membranes crossing the lumen of the trachea A place of predilection for the growth of granulomata is the bifurcation of the trachea with ingrowth in one or both *bronchi* The smaller bronchi are very seldom involved in the process

As a rule the lesions are distributed rather symmetrically although some times growth on one side and destruction and cicatrization (as described below) on the other side may be present very seldom one side only is af fected

A peculiar form of the scleromatous affection of the nose is the *atrophic* or *pseudo ozenic form* clinically resembling *o ena* Scleroma bacteria may be isolated from the nose and the complement fixation test may be positive Of course this does not mark the patient as suffering from scleroma it is pos sible that people with this condition of the nasal mucosa can become carriers more readily than other contacts with a normal mucosa Putschowski thinks that an atrophic stage nearly always precedes the development of the typical granulomatous lesions but the common occurrence of this picture is very much open to question and is denied by many authors According to Burack a care ful examination of these cases of atrophic scleroma usually reveals the pres ence of very small granulations especially at the entrance of the nasal cavity

Fig 301 —Rhinoscleroma Granuloma of upper lip and lacrimal sac

Sometimes the atrophic process is found in a patient who already shows mani fest scleromatous granulomata in the nasopharynx or larynx Others how ever believe that this atrophic mucosa is the only suitable basis for the in vasion and development of the scleroma bacterium in the human nose (Sivak 1941)

From this first localization the scleromatous process may spread along dif ferent paths

1 The *paranasal sinuses* (Highmore s antrum and frontal sinus) may be filled with granulomatous masses severe headache may be the consequence

2 Infiltration of the *upper lip* develops early very characteristic is the formation of a hard sharply circumscribed semicircular swelling under the

tissue, sometimes by ulceration and massive destruction of the tumor, followed by cicatrization In this way, a quiescent stage is reached with large external and internal defects and temporary cessation of the spread of the infection In a single patient all different stages of growth and destruction may be present at the same time

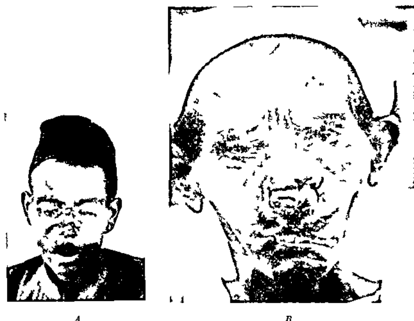
These processes cause the tumefaction to disappear locally, and by the retraction of the newly formed connective tissue new complications may arise In the nose in the later stages of the disease, a very narrow circular stenosis can be found, as a diaphragm or a funnel, consisting of very tough connective tissue, with an opening of only 1 or 2 mm Malformation of the nose and upper lip appear, as may be seen from the accompanying figures, the external nose may disappear, cicatrization of the inflammation in the pharynx, larynx, and trachea likewise can produce stenosis

The clinical picture in this stage can be indistinguishable from that of gangosa (rhinopharyngitis mutilans), but the scleromatous nature of the process can be proved by cultivation of the bacterium, by a positive complement fixation test with rhinoscleroma antigen, by a negative Wassermann reaction, and, finally, by the characteristic pathologic changes in tissue recovered by biopsy from a still active portion of the lesion

From this description it will be plain that the clinical picture can present a great many different aspects Burack, especially, who compiled the descriptions from literature before 1932, gives a very complete list of all possibilities

The clinical picture seems to differ in different countries in Sumatra, Snijders (1931), Kouwenaar et al (1934), and Oomen and Kirschner (1938) found destructive processes not uncommon, whereas Burack rarely observed them on an extensive scale in eastern Europe The chief localizations of the disease may likewise vary, as may be gathered from Table XX, showing the frequency of the different localizations of the disease

TABLE XX



A C T N... ...TIONS					...a Lehm Poland Lwow 457
LOCALIZATION (%)					
Nose	74 1	56 8	72 9	84 6	75 0
Pharynx	51 3	24 5	25 7	27 2	30 0
Nasopharynx	57 2	63 0	60 0	62 9	?
Larynx	72 4	81 7	58 5	62 9	70 0
Trachea	35 0	27 4	?	13 2	6 7
Bronchi	16 3	4 4	?	7 6	1 1

These statistics contain particulars of large numbers of patients all originating from eastern Europe (Poland and the U S S R) The frequencies of observed cases of scleroma of the larynx and especially of the trachea and bronchi differ considerably This difference may be explained, at least par

9 According to the majority of the authors the *cervical lymphatic glands* are enlarged in most cases This may be partly due to the secondary infection following ulceration but several authors (Rona 1899, Sercer 1932) could cultivate the Klebsiella from the glands Pathologic examination showed only subacute unspecific inflammation

The granulomata may grow for many years the spread of the process through the tissues as a rule is very slow but sometimes very rapid growth can be observed Ultimately a serious malformation develops in many cases resulting in the typical Hebra s nose laryngeal stenosis etc

The patients do not suffer unduly from the disease and for a long time disturbances in general health are only slightly marked Complaints of nervousness cold hands and feet and menstrual disorders are often reported

A *B*

Fig 0? —*A* and *B* Rhinoscleroma. Destruction and cicatrization

Comparatively little is known regarding microscopic and biochemical changes in the blood Burack (1932) saw leucocytosis in 10 per cent of his cases only and shift to the left in 60 per cent Severe anemia seldom occurs The sedimentation rate is sometimes high A rise in the calcium and potassium (Kahn 1927) and cholesterin level and an increase of the pH of the blood have been observed especially in severe cases

Emphysema emaciation anemia and finally cachexia are not infrequently found in the final stages in cases with stenosis

In the course of the years many cases show a decrease in size of the granulomata usually by retraction due to the formation of more connective

DIAGNOSIS

The diagnosis is based on the following criteria

1 Clinical Picture

In the majority of cases, the malformation is very typical Physicians with knowledge of the disease can easily differentiate this from tumor, lupus lues, frambesia or leprosy, diagnosis of the last two diseases is frequently made in the tropics by those not familiar with scleroma The residual forms with cicatrization or massive ulcerations may closely resemble lupus or rhino pharyngitis mutilans (gangosa, frambesia) In true gangosa, however, the Wassermann reaction is nearly always positive Polyps of the nose are much softer, they are pedunculated and have a different appearance The initial and *atypical forms, like the atrophic form, are difficult to evaluate, and here* other diagnostic means are of greater importance For a definite diagnosis positive results of the following examinations are necessary

2 Bacteriologic Examination

The Klebsiella must be cultivated from the deeper layers of the tissue, but with this precaution they are found in a large majority of the cases A positive culture greatly supports the diagnosis, however, carriers exist among the immediate contacts of the patients

3 Complement Fixation Tests

The complement fixation reaction was first described by Goldzieher and Neuber (1909), and later confirmed, the technic has been modified by many investigators An extract of *K rhinoscleromatis* is used as antigen According to the general experience, this reaction if performed with sufficient care, is specific Neuber and Adam (1934) saw a positive reaction in 80 to 90 per cent of the manifest cases, Wolff (1934) in 92 5 per cent, Guerkesse and Aloukère (1935) in 95 per cent Unspecific reactions occur rather seldom, Wolff, e g, found them in only 1 per cent of 501 controls According to Alooker (1941) a negative reaction in a suspect patient can be converted into a positive reaction by intravenous injections of tartar emetic

Besides the manifest cases, positive reactions are also found in a number of people *living* in close contact with these patients, just as is the case in finding Klebsiellae It is still un*certain* whether a person with a positive complement fixation reaction is indeed suffering from the disease, that is, developing anatomical lesions, or whether these have developed before It also seems possible that a carrier may develop a positive complement fixation test

The only other disease in which a positive test with scleroma antigen sometimes occurs is *ozena*, Wiraboff (1929) saw 7 per cent positive reactions among 57 patients However, these observations were made in a geographic focus of scleroma, and secondary infection with *K rhinoscleromatis* was found in 6 per cent of his *ozena* patients, 2 of these carriers also had a positive complement fixation test Indeed, *K ozaenae* may have some capsular antigen and even body antigen in common with *K. rhinoscleromatis*

The complement fixation reaction, then, is usually positive in the patients Sometimes contacts are found with a positive reaction but without distinct scleromatous lesions In those cases doubt exists whether these are patients with scleroma or are healthy carriers, contact with the bacterium having re

tially, by a varying thoroughness of the examination But this cannot explain all, for the figures regarding localizations in other organs likewise show marked differences The reason for these differences are unknown, Burack mentions climate and social circumstances

Generally speaking, the cases reported from tropical countries are few and scattered Statistics of Kouwenaar et al (1934) are somewhat different Among 55 cases in Bataks in Sumatra, they saw, in 100 per cent, affections of the nose, in 17 6 per cent, of the pharynx and nasopharynx, and only once a dubious lesion in the larynx One must remember however that all these observations were made in the field under primitive conditions, and that only a part of the patients were examined by an expert laryngologist It is therefore probable that cases of scleroma of the larynx have been overlooked However, it is very striking that the observers did not find a single case of scleroma in which the process had given rise to more or less serious complaints of laryngeal disturbances, dyspnea, stenosis, or even aphonia, and also that on questioning neither the physicians practicing in the endemic area nor the population had any knowledge of patients with these complaints or of any who had died of suffocation Neither do other authors describing scleroma in Indonesians, mention laryngeal involvement, among the extensively published cases (about 100), slight and dubious lesions from the larynx were present in only 3 It seems indeed probable that a difference exists and that scleroma respiratorium in Indonesians has less tendency to attack the larynx and trachea than is the case in Europe

Scleroma respiratorium is a very chronic process, the disease can last for many years It is a disease of young adults, 70 to 80 per cent of the cases observed for the first time occur between the ages of 20 and 35 years, but possibly these infections have existed for many years Children may also be affected The youngest patient observed was 2 years and 7 months old (Burack) According to all statistics, incidence in women is higher than in men (58 5 per cent and 41 5 per cent, respectively, in Belinoff's inclusive statistics, in Indonesia the literature contains descriptions of the disease in 74 women and 31 men patients)

Nothing is known about the period of incubation, nor is it known how the disease is acquired The first symptoms in many cases are likely to cause such slight complaints that the patient is first seen and the diagnosis made many months or even years after the beginning of the disease

Once the infection has begun, the disease may progress slowly for many years, causing granulomata of ever increasing size and number and attacking other regions of the respiratory tract Patients who have had the disease for more than 50 years have been observed (Burack) The prognosis *quoad vitam* is usually favorable, the general health is only slightly impaired There is danger of stenosing processes developing in the larynx, trachea, or bronchi, but if treatment is adequate to maintain the possibility of respiration (by tracheotomy, for instance), life can again be prolonged for years

ported As stated above, focal reaction may be observed even after the nostic intracutaneous injection of Klebsiella, and long continued admir tion of these bacterial suspensions may bring about complete disappea of the granulomata If no success is obtained, preliminary injectio Solganol may be necessary (see skin reaction) Recently Neuber (1941 Belinoff (1941) advised alternating treatment with vaccine and gold pre tions combined with transfusions of blood or serum of convalescent pat

Treatment by drugs has been tried with a large number of preparations cess has been reported from the use of tartar emetic or gold injections p ably in combination with injections of vaccines Reyes (1946) recomn azosulfamide Devine et al (1947) noted disappearance of all clinical toms after 2 months of treatment with streptomycin, the patient recei *total dose of 97 25 Gm of that antibiotic No relapse was seen with* months More experience with these newer remedies is needed

In those cases where the growth of the granulomata, secondary cica tion, or even acute glottis edema endanger life by suffocation, surgical vention will be indicated Stenosis of the larynx or of the upper tr sometimes can be relieved by intubation, but usually the effect is unsati tory and tracheotomy or laryngofissure with removal of the growth electrocoagulation is necessary Plastic operations may be helpful Als stenosing process in the nose, the malformation of the pharynx, and ste of the choanae can be managed surgically Large external tumors ca *ablated Local application of dry ice is advised The prognosis of sur* treatment is uncertain in some patients growth of new granulomata ne tates repeated operations, in others destruction and cicatrization hel diminish the symptoms, and life can be prolonged considerably

sulted in production of antibodies but not in the development of clinical and anatomical symptoms An unspecific reaction is of rare occurrence

The reaction is a very valuable aid in the diagnosis of scleroma Especially in epidemiologic investigations (field work) has extensive use been made of this test

4 Agglutination Test

Agglutination tests with *K rhinoscleromatis* have given inconstant results and have not yet found extensive use According to Neuber and Adam (1934) and Guerkesse and Aloukere (1935) the agglutination test is very specific the latter authors found that the results parallel the complement fixation reaction in 45 out of 52 cases It is necessary to use the bacterial variant without a capsule

When more satisfactory technics are developed the agglutination reaction will probably prove of more importance than at the present time

5 Intracutaneous Allergic Test

*Neuber (1933) saw that a positive cutaneous reaction appears after intra*cutaneous injection of a suspension of the Klebsiellae (prepared by treating dried bacteria with ether) together with a focal reaction The observation however must be prolonged for at least 8 days the reaction occurring during the first 3 days being nonspecific No positive reactions were seen in cachectic patients According to Neuber these patients can be temporarily anergic to the bacteria after injection of a gold preparation (Solganol B Oleosum—Schering) they became allergic and the reaction positive Kuilman et al (1937) also saw satisfactory reactions but other authors could not report consistent results

The intracutaneous reaction needs more confirmation but will probably become a useful adjuvant to the diagnosis

6 Histologic Section

The characteristic pathologic picture in tissue removed by biopsy is usually clear enough to preclude any doubt

TREATMENT

No unanimity of opinion exists as to the best methods of treatment of scleroma Good results have been reported following treatment with x rays or radium often the granulomata decrease in size and are absorbed for the greater part One danger is the formation of cicatricial tissue in the larynx with stenosis and danger of suffocation Radiation must be applied repeatedly for a long time to prevent relapses Reyes (1946) gives 7 applications of roentgen rays (200 KV filter 0 5 mm copper and 1 mm aluminum focal distance 50 cm dose 200 r per day) for 7 consecutive days and repeats these courses of radiation several times over a 2 year period

Administration of polyvalent vaccines made from *K rhinoscleromatis* has been developed by Neuber and very satisfactory results have been re

Key to Family Rickettsiaceae Pinkerton, 1936*

Small bacteriform microorganisms, *often pleomorphic, gram negative,* with staining properties *sui generis,* obligate cellular parasites with distinct grades of specific adaptation for arthropod hosts and susceptible animals

I Obligate cellular parasitism in the sense of not multiplying in the absence of living tissue, not necessarily intracellular

A. Host and vector *Ixodidae,* facultatively intracellular
  Genus I — *R burneti* Derrick, 1939
  R diaporica Cox, 1939
B Vector *Pediculidae,* extracellular
  Genus II — *R wolhynica* Töpfer, 1916
  R weigli Mosing, 1936

II Obligate intracellular parasitism

A. Pathogenic in variable degree for the arthropod vector and for mammals
  Genus III — *Rickettsia*
  R prowazeki da Rocha Lima, 1916
  R mooseri Monteiro, 1931
B Not pathogenic for the arthropod vector (or host)
  1 Pathogenic for mammals
   (a) Host and vector *Trombidiidae*
   Genus IV — *R orientalis* Nagayo et al, 1930
   (b) Host and vector *Ixodidae*
    aa Intracytoplasmic
   Genus V — *R ruminantium* Cowdry, 1925
   R canis Donatien and Lestoquard, 1936
   R ovina Donatien and Lestoquard, 1936
   R bovis Donatien and Lestoquard, 1936
    bb Intracytoplasmic and intranuclear
   Genus VI — *Dermacentroxenus* Wolbach, 1919
   D rickettsi Wolbach, 1919
   R conori Brumpt, 1932
   R pijperi Amaral and Monteiro, 1932
  2 Nonpathogenic for mammals
   (a) Localization in various tissues and organs of the arthropod host, at times causes formation of mycetomas
   Genus VII — *R ctenocephali* Sikora, 1918
   R lectularia Arkwright et al, 1921
   (b) Localization in a single organ, tissue, or cell type
   Genus VIII— *Wolbachia* Hertig, 1936
   W pipientis Hertig, 1936

The entire systematization of the rickettsial group was revised by Macchiavello (1945)

Subsequent to the preparation of this chapter, a new rickettsial disease was described under the name "rickettsialpox" (Refer to Chapter 36)

The etiologic agent of rickettsialpox is *R akari* Huebner, Jellison, and Pomerantz, 1946 *R akari* is morphologically similar to *R prowazeki* and *R mooseri,* diplococcal and diplo bacillary forms have been found It stains well with the Giemsa and the Macchiavello methods but poorly with methylene blue or the Gram stain

Rickettsia burneti and Rickettsia diaporica (the American variety of the *former)* — Cox (1938) described them as lanceolate or bipolar bacilli sometimes diplobacillary some time filamentous Within the cells, in the cytoplasm, are found isolated bipolar or diplo

*Editor's note (O F) Bergey's *Manual of Determinative Bacteriology* (1948) classifies the completely studied Rickettsiaceae which are pathogenic for man as *Rickettsia prowazekii R typhi R rickettsii, R conorii R tsutsugamushi R akari,* and *Coxiella burnetii.*

CHAPTER 35

RICKETTSIOSES OR RICKETTSIAL DISEASES

ATILIO MACCHIAVELLO

(TRANSLATED FROM SPANISH INTO ENGLISH BY ANTHONY DONOVAN)

GENERAL CONSIDERATIONS

Diseases generally classed under the heading "typhus fevers" (or *typhus group of fevers* of English authors) are caused by *rickettsias* and therefore are included under the general heading "rickettsial diseases" or simply "rickettsioses"

RICKETTSIAS

Rickettsioses are diseases caused by rickettsias Pathogenic rickettsias however form only a small group of the large family of Rickettsiaceae Pinkerton 1936 which includes microorganisms interposed between bacteria and filtrable viruses similar to *R prowazeki* described and named by da Rocha Lima 1916 the type species Like bacteria the rickettsias have a definite morphology with perfect individualization of each element Under the electron microscope is seen a limiting cellular membrane quite distinct from the internal protoplasm (Plotz Smadel Anderson and Chambers 1943 Weiss 1943 Mudd and Anderson 1945) They differ from bacteria in that they are not able to live independently—for example in bacteriologic cultures—since preformed substances produced by living cells are necessary for their development (This shows that the enzyme system of the rickettsias is incomplete) They must like filtrable viruses live intracellularly This dependence is not as rigid as it is with viruses for some of the rickettsias live extracellularly like *I burneti* and *R quintana* or *wolhynica* although with definite dependence upon the metabolism of certain types of cells Their intracellular life demands that they be related to hosts and reservoirs and when pathogenic to vectors There is a tendency to accept as true rickettsias only those related to an arthropod host temporary or permanent the permanent host being the natural reservoir Other reservoirs are found among the higher vertebrates especially rodents

The same rickettsia may show different grades of adaptation for different arthropods or mammals When the adaptation to an arthropod is perfect the rickettsia is hereditary when it is imperfect the insect becomes ill and may die as in the case of *Pediculus humanus* infected with *R prowazeki*

Our knowledge of rickettsias is incomplete definition and classification is therefore difficult It is understandable that the pathogenic types are the best known

THE RICKETTSIAS AND THEIR CLASSIFICATION

TABLE XXI CLINICAL ETIOLOGIC CLASSIFICATION OF THE RICKETTSIOSES

ETIOLOGIC AGENT	GROUPS OF RICKETTSIOSES (CLINICAL CLASSIFICATION)	DISEASES COMPRISING EACH GROUP
	I *Nonexanthematic rickettsioses or with evanescent exanthemata*	
1 *R burneti*	1 Not recurrent	Australian "Q" fever
R diaporica		American "Q" fever
2 *R wolhynica*	2 *Recurrent*	*Trench fever or quintana fever*
	II *Exanthematic rickettsioses*	
	A *Human*	
3 *R prowazeki*	1 Petechial exanthematic rickettsiosis	Classical exanthematic typhus fever—Brill's disease
R mooseri		Exanthematic murine typhus
4 *D rickettsi*	2 Macular exanthematic rickettsiosis	Spotted fever
R conori	3 Boutonneuse exanthematic rickettsiosis	Boutonneuse fever
R pijperi		South African tick fever
5 *R orientalis*	4 Maculopapular exanthematic rickettsiosis	Scrub typhus
	B *Animal*	
6 *R ruminantium*	1 Reticuloendothelial rickettsiosis	Heartwater disease of cattle
7 *R canis*	2 Monocytic rickettsiosis	Canine typhus

The foregoing clinical classification does not consider epidemiologic variants nor virulence nor geographic localization which are apart from clinical criteria.

TABLE XXII RELATIONSHIP BETWEEN THE RICKETTSIOSES

RICKETTSIOSES	INITIAL ULCER	EXANTHEMA	VECTOR	WEIL FELIX REACTION	SPECIFIC COMPLEMENT FIXATION TEST
1 Nonexanthematic and nonrecurrent rickettsioses					
"Q" fever	0	0	Not necessary	0	Yes
2 Recurrent rickettsioses					
Trench fever	0	0	Louse	0	?
3 Exanthematic rickettsioses		0			
a Petechial					
Classic exanthematic typhus	0	Petechial	Louse	OX19+++ OX2+	Yes
Murine typhus	0	Petechial	Flea and rat louse	OX19++ OX2+	Yes
b Macular					
Rocky Mountain spotted fever	0	Macular	Tick	OX19+ OX2+ OXK+	Yes
c Papular					
Boutonneuse fever	+	Papular	Tick	OX19+ OX2+	Yes
d Maculopapular					
Scrub typhus	+	Maculopapular	Mite	OXK+++	Yes

bacillary forms or groups of rickettsias in rounded masses although some of these masses may show less different stated organisms of a coccoidal or granular type In animals as well as in tissues or egg cultures the organism grows and develops well extracellularly. Morphologically it is similar to *R prowazeki* although somewhat larger which may be due to the fact that it stains more intensely with Giemsa and with the Macchiavello stain

Rickettsia wolhynica—The morphology in mammals is diplococcal or diplobacillary and in lice in addition oval or round with polar staining (Töpfer) larger more nearly oval shorter thicker and at the same time less pleomorphic than *R prowazeki* The organisms are grouped in layers or palisades on the intestinal epithelium of the louse for which they are not pathogenic It stains more easily and more intensely than the rickettsia already mentioned It is not known for certain whether or not it is hereditary in the louse

Rickettsia prowazeki and Rickettsia mooseri—In mammals it is paired coccoid or lanceolate (Wolbach Todd and Palfrey 192) In lice it is extraordinarily pleomorphic according to da Rocha Lima In tissues (cultures) it is paired lanceolate and less frequently filamentous (Nigg 1930 Zinsser and Macchiavello 1936) With Giemsa stain it usually shows a halo and in the so called multiplying forms demonstrates red and blue staining material In peritoneal exudates of rats and in tissue cultures the author has observed filamentous forms of 1 and 1 microns and longer There is no morphologic difference between *R prowazeki* and *R mooseri* although the latter is more diffused in the tissues of susceptible animals and grows more easily in tissue cultures As with all the rickettsias except *R burneti* and its variant *diaporica* it is not filtrable It is not hereditary in the louse which it dies when the parasitization of the epithelial cells of the digestive tract produce distention rupture and desquamation of the tract In mammals it lives in the cytoplasm of the endothelial cell The murine variety prefers the serosal cells of the tunica vaginalis of rats The typical cellular form was described by Pinkerton in 1936 and before as a growth en masse of organisms It has been cultivated in the louse by Weigl (1920) in tissues the plasma by Wolbach and Schlesinger (1923) Zinsser and Batchelder (1930) and Pinkerton and Hass 1931) in cultures by Maitland and modified Maitland method by Nigg and Landsteiner (1930 1931) Hilgler and Aschner (1934 Zinsser and Macchiavello (1936 in the agar Zinsser Weiss and Fitzpatrick (1938 1939) in eggs by Cox (1939) in the vitelline sac and on the chorioallantoic membrane by Zia (1934

Dermacentroxenous rickettsia—In mammals it is paired frequently surrounded with a halo in lanceolate form with or without polar granules and rounded In the tick it is more pleomorphic and with the bacillary form type without chromatoid granules are found lanceolate diplobacilli and small intranuclear rods with chromatoid granules (Wolbach et al 1922) The lanceolate type is similar to and has large as a pneumococcus and is not like the form of *R prowazeki* In ticks it is found all through the tissues In tissue culture Pinkerton (1936 found multiplication scant in the cytoplasm but abundant in the nucleus the morphology being distinct for each localization To the three types described by Wolbach a fourth (Spencer and Parker 1940) has been added This is not infectious but produces immunity

R brasiliensis is synonymous with *D rickettsi* *R conori* of boutonneuse fever and *R pijperi* of South African tick fever are morphologically similar to *D rickettsi*

Rickettsia orientalis—This is a short diplobacillus with bipolar staining (0 3 to 0 by 0 8 to 2 0 microns) It grows diffusely in cell cytoplasm but does not distend the cells It can be seen easily if the anterior chamber of the eye of experimental animals is inoculated and Descemet s membrane examined It does not grow intranuclearly

Attempts to classify the rickettsial diseases have been numerous some being clinical (P Jorge 193
some utilizing
the primary tr
multiple criteria such as epidemiology pathology serology immunology clinical characteristics etc among them being those of Amaral and Monteiro (1931) Brumpt and Deutschman (1936) Burnet (193) Zinsser (193) Castañeda (1942) and Plotz and Wertman (1945)

As was to be expected, America could not be kept free from typhus, and first the *Conquistadores* and later the colonists and immigrants were the cause of serious epidemics. In Mexico the disease has been recognized since 1530, in Chile since 1554 (Rosales), in Colombia since 1630 ("the plague of Santos Gil"), in Peru since the beginning of the Conquest. In Canada and the United States, it is mentioned in Quebec and Montreal, 1820, Halifax, 1827, Boston, 1838 and 1847, New York, 1818, 1825, 1837, 1852, 1861-65, 1881, and 1892, Philadelphia, 1827, 1836, 1847, 1864, and 1880, New Orleans, 1847, with some recent epidemic outbreaks in Iowa (Boyd, 1917), California (Cumming and Senftner, 1917), and New Mexico (Armstrong, 1922), the latter possibly originating in Mexico. Among the Indians of South and Central America, as in Mexico, typhus is endemic; not so in the United States, where there is mentioned only one serious outbreak, among the Navajo Indians, on the San Juan Reservation, New Mexico, 1920-1921.

In Africa, typhus has occurred since time immemorial in the northern Mediterranean zone. Recently, in Uganda (1932), Transvaal, Union of South Africa, and in Basutoland, important outbreaks have occurred. In Asia, typhus has been definitely recognized only recently.

The enormous number of references available in relation to classical exanthematic typhus contrasts with the scanty information to be found on the other rickettsial diseases, with reference to history as well as incidence. This is understandable, as most of the rickettsias are local diseases of an endemic or sporadic character, without much influence on the political, social, or economic lives of the people, and without dramatic aspects which spontaneously attract attention.

In 1837 (Gerhardt), typhus was definitely distinguished from typhoid fever (Stille, also, 1838), this being the first decisive advance in the study of rickettsial diseases.

Palm (1878) and Baelz and Kawakami (1879) described for the first time Japanese river fever, although it is supposed that the disease (tsutsugamushi) had been known for 1,000 years. Ten years later Maxey (1899) identified Rocky Mountain spotted fever, although about 1873 it had been described in the vicinity of the Snake River, Idaho.

There were established, then, the three predominating groups of exanthematic rickettsioses, although their etiologic relationship was not realized at the beginning, nor were they always clinically differentiated in the places where they existed together. Spotted fever, in the United States, was the first rickettsiosis in which important results were obtained in experimental studies. In 1902, it was observed in the Bitterroot Valley of Montana, with a high mortality, of 70 to 80 per cent. Wilson and Chowning immediately proved *Dermacentor andersoni* as its transmittor, a supposition confirmed by McCalla (1905) who transmitted the disease from man to man by ticks removed from patients, and by Ricketts (1906) who in turn transmitted it to laboratory animals—monkeys and guinea pigs—being unaware of the experiment already mentioned, which was not published until 1908. Previously (1906), Ricketts had proved the susceptibility of these animals to spotted fever, in 1907, he demonstrated the hereditary character of the infection in ticks, and, in 1909, he believed that he saw the specific infecting microorganisms in the blood of human beings, guinea pigs, and monkeys with the disease and in the tissues of the vector.

Nicolle, Comte, and Conseil (1909) demonstrated that typhus is transmitted by lice, and also showed the susceptibility of guinea pigs and monkeys to experimental infection, facts confirmed by Ricketts and Wilder (1910) while working with Mexican typhus *(tabardillo)*. Again they thought they could see the etiologic agent of typhus in preparations from the blood of patients and from the intestinal contents of lice. By means of cross immunity experiments they showed that typhus and spotted fever are different diseases. From 1898 until 1910-1911, Brill, in a series of notable studies, emphasized the epidemiologic and clinical differences between typical exanthematic typhus and cases of the disease which today bears his name, sporadic cases seen in New York and Boston, which Anderson and Goldberger (1912) proved to be attenuated forms of typhus.

During the following years, experiments were concentrated on the etiologic agent of typhus, 30 or more microorganisms being suspected. It is possible that Hegler and Prowazek

HISTORICAL NOTES ON RICKETTSIAL DISEASES

GEOGRAPHIC DISTRIBUTION

The rickettsial disease group has been increasing continuously while at the same time investigative methods have been improved, particularly those related to the etiology

No clinical or epidemiologic description extant assures us that the rickettsioses were known by Hippocrates or other physicians of ancient times In the Cronica Cavense of the year 1083 (a monastery near Salerno), there is mentioned "a fever accompanied by petechias," the first reference which makes one suspect exanthematic typhus Up to 1490, in Spain, typhus played a prominent role in the war between the Saracens and the Spaniards, and during the siege of Granada, typhus broke out in epidemic form, taking a toll of 17,600 victims among the soldiers The medical historians of the period (Luis de Toro, 1574, López de Corella, 1574 Mercado, 1574, Carmona, 1582 Pérez 1590, Martínez de Leiva, 1597, Bocungelino, 1600, and Soria, 1635), whose works have been reviewed by Villalba (1802), believed that typhus was introduced into the Iberian peninsula by Spanish soldiers infected on the Isle of Cyprus, from then on giving rise to a great number of epidemic outbreaks and extending to America in Mexican territory simultaneously with the conquests of Hernán Cortéz

In 1546, Geronimo Fracastorio described typhus in a masterly manner in Chapter VI of Volume II of "*De Contagione*," referring to the epidemics in Italy during the years 1505 and 1528 Zinsser (1935) stressed the importance of this episode, saying "In 1530, Charles V was crowned ruler of the Roman Empire at Bologna, by the power of typhus fever"

The relationship of typhus to war, famine, migrations, political, social, and economic upheavals, and other public calamities was early recognized in history Charles V, himself, in 1552 was forced to give up the siege of Metz because his army was greatly reduced in numbers by typhus From 1618, the beginning of the Thirty Years' War, until 1630, typhus dominated the entire continent of Europe In Hungary, its incidence was such that it was called *morbus hungaricus* Its frequency in political prisons gave it the name *morbus carcerorum* Lazarus Riverius (1623) described the first epidemic in France, in Montpellier, as *febris maligna pestilens*, which was repeated in Lyons and Limogès, in 1628 (with 60 000 and 25 000 deaths, respectively), in Poitiers in 1651, and in Burgundy in 1666

In England from the first, typhus was associated with prisons (jail fever), and the judgments against prisoners parasitized with lice (*Black Assizes*) caused repeated epidemics, such as the well known epidemic at Oxford University in 1577, which cost the lives of 510 persons, among them 100 members of the University In 1643, according to Willis, it destroyed great numbers of individuals in Parliament and the Royal Army during the siege of Reading In Ireland the so called *Irish ague* occasioned the outbreak of Cork, 1708, and later the epidemics of 1718, 1729, 1735, 1740, and 1797 During the entire eighteenth century, typhus scourged Europe Moscow in 1730, Germany in 1740, Flanders in 1743, Spain in 1762, Naples in 1764 During the Seven Years' War, the French Revolution, the Crimean War, the Napoleonic campaigns, especially that in Russia, and later, during economic depressions in Silesia, 1846, and London 1862, typhus greatly reduced in numbers the armies and civilian populations until the middle of the nineteenth century, when it began to decline In the Franco Prussian War it had a secondary role Finally it was restricted to the Balkans and Russia until World War I in 1914

Typhus began in Serbia with extraordinary virulence At one time 2 500 cases were isolated daily in military hospitals alone In the postwar period, it is calculated that there were between 6,000 000 and 10,000,000 cases in Russia within 4 years

Advances in the prophylaxis of the disease were seen during the Italian conquest of Abyssinia, where African troops, according to Castellani, had more than 20,000 cases, with not a single one among the European troops World War II is another example of the fact that typhus is no longer necessarily a disease of armies Statistical data, on the other hand, show the damage it still does among civilian populations of belligerent or occupied countries

Japanese river fever and investigations on the larvae of *Trombicula akamushi* the red mite (Ashburn and Craig, 1908, in the Philippines, Breinl, Priestly, and Fielding, 1914, in North Queensland, Dowden, 1915, in the Malay States, Hatari, 1921, in Formosa, Lagrange, 1923, in Annam)

By 1926 the studies of Maxcy managed to break the unity of exanthematic typhus, which had not been destroyed by the researches of Brill On epidemiologic grounds he showed that the endemic typhus of the southern part of the United States has a direct relationship with rats and their ectoparasites Mooser (1928) established a diagnostic sign in guinea pigs inoculated experimentally with virus of Mexican typhus (Mooser's sign) Dyer et al (1931) obtained murine virus from fleas of rats caught in Baltimore, and Mooser, Castañeda, and Zinsser (1931) obtained murine virus from brains of rats trapped in the prison of Belen, Mexico The former transmitted the infection from rat to rat by means of fleas, and the latter by means of rat lice Murine virus is obtained in the most diverse countries, in Syria, Greece, Tunis, Chile, Manchuria, Malay States, Russia, etc At first the endemic character of murine typhus caused it to be confused with the sporadic disease described by Brill, this was clarified by the work of Zinsser (1934), who proved the classical nature of the disease in the northeastern part of the United States and characterized it as recurrent typhus At first, the lack of comparative studies of the various viruses discovered gave rise to new terminology, generally of a geographic character, causing much confusion, on the one hand, and on the other, demonstrating the incorrectness of considering Mexican typhus as the equivalent of murine typhus The designation *endemic typhus* for the recently discovered disease and *epidemic* for classical typhus also appeared to be inadequate when it was considered that the murine virus could become epidemic if implanted in man and transmitted to other individuals by means of lice Zinsser thought that if, originally, typhus was a disease of rats, and that if the latter invaded Europe only with the return of the Crusaders (as the first unmistakable reference to rats is made in the works of Giraldus Cambrensis, 1147 1223), it is entirely possible that the epidemic typhus of the Middle Ages and of today is really a new disease of mankind, which would explain why it is not mentioned in ancient classical medical treatises

In its turn, Rocky Mountain spotted fever also lost its unity when, in 1930, the so called "Eastern type" was discovered, in contrast to the classical type of the West In 1932, Reimann, Ulrich and Fisher mentioned the Minnesota variety In 1928, Piza, Meyer, and Gomes first described the typhus of São Paulo In 1933, a similar affection was reported in Minas Geraes In 1935 Pijper and Dau studied African tickbite fever Patiño, Afanador and Paul described, in 1937, a focus of petechial fever in Tobia, Colombia Recent laboratory studies indicate that all these diseases represent at most simple variants of Rocky Mountain spotted fever, and, including boutonneuse fever of the Mediterranean, have close generic connections with it (Parker and Davis, 1933, Dyer, 1933, Badger, 1933, Haas and Pinkerton, 1936, Amaral and Monteiro, 1931, Monteiro, 1933, Dias and Martins, 1937, etc)

In connection with tsutsugamushi, scrub typhus, and other variants of the fevers transmitted by mites, the investigations of Lewthwaite and Savoor (1936), as well as the recent studies of American Army doctors stationed in the Far East, should be mentioned as being outstanding in determining the unity of the group and the local variants

During recent years we have witnessed a better understanding, as well as a greater extension, of a curious disease, "Q" fever, which should more properly be called "burnetiosis" Discovered in Australia, as a disease associated epidemiologically with ticks and rodent vectors, it has been finally determined to be a sickness transmitted principally from man to man, giving origin, at times, to explosive epidemics of atypical pneumonias, often called "Balkan grippe"

Also, while World War II afforded new and unexpected fields for the investigation of rural typhus (scrub typhus, tsutsugamushi fever) in the South Pacific theater of operation in the heart of New York City there appeared a new rickettsiosis, resembling in appearance chicken pox, which forms by itself an entity unmistakable among its analogous diseases—rickettsialpox The history of this disease is instructive and offers a field for interesting speculations, on which, unfortunately, we cannot enlarge in this place (See Chapter 36)

(1913), Sergent, Foley and Vialatte (1914) and Nicolle, Blanc and Conseil (1914) saw the organism in the feces of lice collected principally on individuals with typhus, but the merit of describing, naming and proving the etiologic role of *R. prowazeki*—so named in honor of the two martyrs to typhus, Ricketts and Prowazek—belongs entirely to da Rocha Lima. Da Rocha Lima created the genus *Rickettsia* and clearly defined its morphology, its connection with the louse vector, its staining properties, its differentiation from the bacteria, the stages in its intracellular development in the intestinal cells of the louse and the relationship of this coexistence with human infection.

The studies of da Rocha Lima represent a notable contribution to our knowledge of rickettsial disease and an example of scientific work carried out without any vacillation in the face of a great many contradictory conditions, many of which at the time appeared to be true. In reality, during the period 1914 to 1916, in the midst of World War I, the opportunities for working on typhus increased, but at the same time investigations were complicated by a series of scientific discoveries quite difficult to interpret. Plotz (1915) had described as the etiologic agent a microorganism which seemed to fulfill all the requirements for specificity. Nicolle proclaimed the possibility that typhus was an infection caused by a filtrable virus. Various authors denied or doubted the bacterial nature of rickettsias or of their pathogenicity. Experiments on lice were made difficult by the lack of knowledge of the histology and biology of the insect and also by the contamination of the colonies with nonspecific and nonpathogenic rickettsias (*R. pediculi*). The Weil-Felix reaction lent support to the suggestion of an etiologic connection between typhus and *Proteus*. Last, trench fever and its possible cause, *R. wolhynica* or *quintana*, a parasite of the louse, added more confusion to that already mentioned. During that period the knowledge of rickettsias was broadened by the successive and rapid discoveries of new species (*R. melophagi*, *R. lectularia*, *R. ctenocephali*, etc.), these findings culminating with the work of Cowdry (1923, 1925) and of Wolbach and his school. Wolbach (1919) established definitely the etiologic role of rickettsia in spotted fever, creating and defining the new genus *Dermacentroxenus*, and in 1922, with Todd and Palfrey, contributed irrefutable proofs for establishing the specificity of *R. prowazeki* as the cause of typhus. In addition, his notable studies in pathology amplified the classical work of Popoff (1875), Fraenkel (1914, 1915), Prowazek (1915), Aschoff (1915), Ceelen (1916), Jaffé (1918), Grzywo-Dabrowski (1918), Herzog (1918), Nicol (1919), Spielmeyer (1919) and many others and demonstrated the presence of rickettsias in the typical lesions (1920, 1922).

During the decade 1910-1920 five other important events merit being mentioned. The first was the discovery of a new exanthematic disease, nodular scarring fever, recognized by Conor and Bruch (1910) in Tunis and later found at numerous points on the coast of the Mediterranean and finally found to be identical with Kenya fever. The second was the opportunity offered by World War I (1914-1918) to prove epidemiologically the role played by the louse as vector of typhus and to base prophylaxis on measures for eradicating this parasite. The third was the incorporation of the Weil-Felix reaction, using *Proteus* OX, in diagnostic measures for typhus, a reaction which has been extended to the other exanthematic rickettsioses and which, thanks to the accidental finding of the Kingsbury strain, served later on in the hands of Felix and Rhodes to form the basis for a serologic classification of the diseases of this group. (Incidentally, the antigenic nature of rickettsias was surmised by means of comparative studies with *Proteus* X.) The fourth event was the discovery and description of trench fever (quintana or Wolhynian fever), possibly caused by *R. wolhynica*, a disease which reached epidemic proportions between 1915 and 1918 among the warring armies. Recognized first in Flanders and France by Graham, Hunt and Rankin, it soon was found in Poland, Austria, Italy, Greece, Egypt and elsewhere. Although experiments demonstrated

lead to no positive conclusions as to the true nature of the disease and its relationship with other rickettsias. Finally, it is important to note in this decade another event of no less value than those already mentioned, the multiplication of studies on diseases similar to

laboratories of the United States Public Health Service Perhaps the most important human outbreak so far was one which occurred in a group of 1,638 soldiers who returned to the United States from Italy, one third of the men were infected, apparently before leaving for America, in the airdrome of the base of Grottaglie The first South American case was recently diagnosed in Panama

From the foregoing it is clear that "Q" fever has a wider geographic distribution than heretofore suspected, and the geographic designations of "Australian" and "American" varieties have no foundation to warrant their continued use

Epidemiology

In Australia the disease was first seen in Brisbane, about 1937, and possibly earlier (1935) and was described by Burnet This writer, with Freeman, Dyer, and others, studied the epidemiology of "Q" fever and established the true cycle of infection in vectors and reservoirs, and an accidental cycle involving man only by chance

The aerial spread of the disease and its remarkable diffusion explain why these accidental infections may affect groups of individuals subjected to the same ambient conditions The possibility of contagion from person to person by the respiratory tract (dispersion of droplets of saliva and sputum) has not been proved

Mass infection by the aerial route, which is characteristic of the laboratory infections seen in the United States (Fort Bragg), is not intrinsically different from the infection observed in abattoir workers in Brisbane, and in Amarillo, Texas, and the outbreak which began in Grottaglie is similarly related to this group On the other hand, the true cycle of "Q" fever in rodents and vectors has not been established in the United States, *it being known only that D andersoni is the carrier of the virus*

In Australia the zootic cycle of "Q" fever includes a reservoir (the bandicoot *Isoodon torosus*), a vector which transmits among the bandicoots *(Haemaphysalis humerosa)* a vector from these to young cattle *(Ixodes holocyclus)*, and a disseminator from the latter to adult cattle *(Boophilus annulatus)*, and among adult cattle *(Haemaphysalis bispinosa)* (Derrick, 1944) Since *R burneti* multiplies in the digestive canal of the tick, parasitizing the cells, as do other rickettsias, it passes to the feces as soon as a rupture of these cells occurs Feces accumulate in the hair of the cattle, and then the workmen who handle the hides in the abattoirs become infected from these feces In this respect "Q" fever of the Brisbane abattoir is a true occupational disease

In the United States *R diaporica* was isolated in Montana by Davis and Cox (1938) in *D andersoni* collected at Nine Mile Creek, this being an example of an infectious agent discovered prior to recognition of the disease Parker and Davis (1938) showed that the rickettsia is hereditary in the tick, and they achieved experimental transmission with ticks In 1939, Davis isolated three new strains of *D andersoni* in Wyoming The following year he found that in *Ornithodorus turicata* the virus could survive for 1,001 days, without being transmitted by the bite, nor hereditarily, although passing to the feces Cox (1938) isolated, cultivated, and described the virus and its properties and described the experimental disease Parker and Steinhaus (1943) observed that the rickettsia could live for about 3 months in the organs of convalescent guinea pigs Studies directed toward recognition of the natural reservoirs of the disease and the existence of other vectors have not been carried out, nor is there complete *knowledge of the probable cycle, as mentioned in Australia*, a cycle which must exist, inasmuch as the outbreak in Amarillo (Irons et al, 1946) involved about 40 individuals working in cattle corrals and in a meat cannery*

In the outbreaks recently described in Italy and elsewhere, an intimate relationship between cases and certain animals, such as swallows, rats, mice, and cattle, as well as deposits

*Editor's note (O F) Since this chapter has been in press *Q fever has been found* all over the U S A (Strauss and Sulkin Am J Pub Health 39: 492 1949)

Techniques used in the study of the rickettsioses have undergone radical changes and have been enriched with methods more exact than those of scarcely 20 years ago, when the Weil Felix reaction and animal inoculation dominated this field

The veritable chaos which existed only 10 years ago with regard to classification of the rickettsial diseases and relationships among them is disappearing, thanks to application of the methods of investigation mentioned above To Megaw must be accorded the honor of being possibly the first to suggest a logical grouping and classification of the rickettsioses Definitive classification will come with more detailed knowledge of the antigenic constitution of the rickettsias and of their mutual inter relationships

CLINICAL ASPECTS EPIDEMIOLOGY AND PATHOLOGY OF THE RICKETTSIAL DISEASES

I NONEXANTHEMATIC RICKETTSIOSES

1 "Q" FEVER

Synonyms—Australian "Q" fever American "Q" fever, Nine Mile fever, pneumonitis diaporica burnetiosis, Queensland fever

Definition

"Q" fever is a rickettsiosis caused by *R burneti* and its variant *R diaporica*

General Considerations

The term "Q" fever is derived from the region of Queensland, Australia, where the disease was originally observed The term could advantageously be replaced by the name "burnetiosis " as proposed by Macchiavello (1945) * Both "Q" fever and trench fever are among those rickettsioses which are non exanthematic or which exhibit only a transitory exanthem "Q" fever is differentiated clinically from trench fever by its lack of recurrent characteristics

The Australian and the American varieties of "Q" fever are intimately related, the causative agent of each disease having the same antigenic constitution although varying in virulence The apparently different epidemiology of the two varieties does not depend on intrinsic peculiarities of the infectious agent but rather on differences in reservoirs and vectors and in the routes and methods of propagation of the infection The portal of entry of the virus is of preponderant importance in determining the modality of the clinical picture

For many years the disease was known only in Australia as a natural infection, and in the United States accidental infections occurred among laboratory workers In 1946, the disease appeared in Amarillo Texas, in cattle handlers and showed the characteristics of a spontaneous infection

On the other hand 8 outbreaks of "Q" fever were observed among the allied troops in Italy, Greece, and Corsica during 1944 and 1945 Five of these were thoroughly studied and in 3 *R burneti* was recovered in laboratory animals A laboratory outbreak at Fort Bragg, attendant upon the manipulation of infected chick embryos, was similar to outbreaks seen in the

of hay accumulated in the attics of rural dwellings has been suspected In the Grottaglie epidemic an extrahuman source of infection along with an unknown intermediary factor, was suspected

In 1939 Dyer established the identity of the Queensland disease with that of Montana demonstrating minor differences that American "Q" fever does not infect monkeys that it produces a local reaction in the skin of guinea pigs at the point of subcutaneous inoculation and that it is more virulent for laboratory animals. The immunologic identity was proved by Bengtson in 1941 she also studied the possibilities of vaccination and passive protection with immune serum

Many facts are still unknown in our epidemiologic knowledge of this disease

In the first case of Q fever which occurred in the United States (Dyer 1938), in the Montana Laboratory the epidemiology was not established with certainty In the following outbreak in Washington D C which occurred in the laboratories of the United States Public Health Service in 1940, Hornibrook and Nelson studied the 15 cases of pneumonitis which developed among the 153 employees of the National Institute of Health. The source of infection was not established although direct transmission by arthropods was disproved and the possibility of droplet infection appeared more likely In these cases as in the first one the isolation of the rickettsia and the serologic reactions left no doubt as to the nature of the disease and its similarity with the Australian infection (Dyer, Topping and Bengtson)

Clinical Symptoms

There have been a sufficient number of observations at the present time to permit a general description of the clinical aspects of the disease In many of the cases described previously as having no pneumonitis despite the evident infection by the respiratory route it is possible that the pulmonary localization was not perceived Nevertheless while awaiting more complete studies it is desirable to describe the clinical pictures seen in various outbreaks independently

In Australia Q fever was described by Derrick (1937) as an acute febrile disease of man of low mortality resembling an attenuated form of typhus and with an evolution of 7 to 24 days' duration The beginning is sudden with fever rising to 40° C and after marked daily remissions ends in crisis generally at the end of 1 week Typical cases have headache malaise anorexia conjunctival injection photophobia backache and pains in the extremities and bradycardia An exanthem was seen in only 1 of 9 cases The blood shows no changes and the Weil Felix reaction is always negative In certain cases the disease runs a more chronic course

In the case of Dyer (1938) which occurred in May of that year a probable incubation period of 10 to 16 days was suspected The sickness began with pains in the eyeballs tiredness and general malaise In the days following there were chills and slight fever for 4 or 5 days On about the fifth day these symptoms ceased and the patient had profuse sweating at midnight a crisis which was repeated on 4 consecutive nights Aside from certain dental and joint pains (fingers) the patient felt well had a normal appetite and slight constipation The pulse rate fluctuated between 72 and 90 The hemogram and urinalyses were normal except for slight indications of albumin in the urine and blood culture and serum agglutination tests for typhoid brucellosis and tularemia were negative A Weil Felix reaction of 1 160 was

laboratories of the United States Public Health Service Perhaps the most important human outbreak so far was one which occurred in a group of 1 638 soldiers who returned to the United States from Italy, one third of the men were infected, apparently before leaving for America, in the airdrome of the base of Grottaglie The first South American case was recently diagnosed in Panama

The aerial spread of the disease and its remarkable diffusion explain why these accidental infections may affect groups of individuals subjected to the same ambient conditions The possibility of contagion from person to person by the respiratory tract (dispersion of droplets of saliva and sputum) has not been proved

Mass infection by the aerial route, which is characteristic of the laboratory infections seen in the United States (Fort Bragg), is not intrinsically different from the infection observed in abattoir workers in Brisbane, and in Amarillo, Texas, and the outbreak which began in Grottaglie is similarly related to this group On the other hand, the true cycle of "Q" fever in rodents and vectors has not been established in the United States, it being known only that *D andersoni* is the carrier of the virus

In Australia the zootic cycle of "Q" fever includes a reservoir (the bandicoot *Isoodon torosus*) a vector which transmits among the bandicoots *(Haemaphysalis humerosa)* a vector from these to young cattle *(Ixodes holocyclus)*, and a disseminator from the latter to adult cattle *(Boophilus annulatus)*, and among adult cattle *(Haemaphysalis bispinosa)* (Derrick, 1944) Since *R burneti* multiplies in the digestive canal of the tick, parasitizing the cells, as do other rickettsias, it passes to the feces as soon as a rupture of these cells occurs Feces accumulate in the hair of the cattle, and then the workmen who handle the hides in the abattoirs become infected from these feces In this respect "Q" fever of the Brisbane abattoir is a true occupational disease

In the United States *R diaporica* was isolated in Montana by Davis and Cox (1938) in *D andersoni* collected at Nine Mile Creek, this being an example of an infectious agent discovered prior to recognition of the disease Parker and Davis (1938) showed that the rickettsia is hereditary in the tick, and they achieved experimental transmission with ticks In 1939, Davis isolated three new strains of *D andersoni* in Wyoming The following year he found that in *Ornithodorus turicata* the virus could survive for 1,001 days, without being transmitted by the bite, nor hereditarily, although passing to the feces Cox (1938) isolated, cultivated, and described the virus and its properties and described the experimental disease *Parker and Steinhaus (1943) observed that the rickettsia* could live for about 3 months in the organs of convalescent guinea pigs Studies directed toward recognition of the natural reservoirs of the disease and the existence of other vectors have not been carried out, nor is there complete knowledge of the probable cycle, as mentioned in Australia, a cycle which must exist, inasmuch as the outbreak in Amarillo (Irons et al, 1946) involved about 40 individuals working in cattle corrals and in a meat cannery *

In the outbreaks recently described in Italy and elsewhere, an intimate relationship between cases and certain animals, such as swallows, rats, mice, and cattle, as well as deposits

*Editor's note (O F) Since this chapter has been in press Q fever has been found all over the U S A (Strauss and Sulkin Am J Pub Health 39 49? 1949)

of hay accumulated in the attics of rural dwellings has been suspected In the Grottaglie epidemic an extrahuman source of infection, along with an unknown intermediary factor was suspected

In 1939, Dyer established the identity of the Queensland disease with that of Montana demonstrating minor differences that American " Q " fever does not infect monkeys that it produces a local reaction in the skin of guinea pigs at the point of subcutaneous inoculation and that it is more virulent for laboratory animals The immunologic identity was proved by Bengtson in 1941 she also studied the possibilities of vaccination and passive protection with immune serum

Many facts are still unknown in our epidemiologic knowledge of this disease

In the first case of Q fever which occurred in the United States (Dyer, 1938), in the Montana Laboratory the epidemiology was not established with certainty In the following outbreak in Washington, D C which occurred in the laboratories of the United States Public Health Service in 1940 Hornibrook and Nelson studied the 15 cases of pneumonitis which developed among the 153 employees of the National Institute of Health The source of infection was not established although direct transmission by arthropods was disproved and the possibility of droplet infection appeared more likely In these cases as in the first one the isolation of the rickettsia and the serologic reactions left no doubt as to the nature of the disease and its similarity with the Australian infection (Dyer, Topping and Bengtson)

Clinical Symptoms

There have been a sufficient number of observations at the present time to permit a general description of the clinical aspects of the disease In many of the cases described previously as having no pneumonitis despite the evident infection by the respiratory route it is possible that the pulmonary localization was not perceived Nevertheless while awaiting more complete studies it is desirable to describe the clinical pictures seen in various outbreaks independently

In Australia Q fever was described by Derrick (1937) as an acute febrile disease of man of low mortality resembling an attenuated form of typhus and with an evolution of 7 to 24 days' duration The beginning is sudden with fever rising to 40° C and after marked daily remissions ends in crisis generally at the end of 1 week Typical cases have headache malaise anorexia conjunctival injection photophobia backache and pains in the extremities and bradycardia An exanthem was seen in only 1 of 9 cases The blood shows no changes and the Weil Felix reaction is always negative In certain cases the disease runs a more chronic course

In the case of Dyer (1938) which occurred in May of that year a probable incubation period of 10 to 16 days was suspected The sickness began with pains in the eyeballs tiredness and general malaise In the days following there were chills and slight fever for 4 or 5 days On about the fifth day these symptoms ceased and the patient had profuse sweating at midnight a crisis which was repeated on 4 consecutive nights Aside from certain dental and joint pains (fingers) the patient felt well had a normal appetite and slight constipation The pulse rate fluctuated between 72 and 90 The hemogram and urinalyses were normal except for slight indications of albumin in the urine and blood culture and serum agglutination tests for typhoid brucellosis and tularemia were negative A Weil Felix reaction of 1 160 was

related to a former attack of typhus and with vaccination against Rocky Mountain spotted fever The "X" strain of *R diaporica* was isolated from the blood

In the 15 cases described by Hornibrook and Nelson (1940), the disease was characterized by a sharp onset but was mild, a few cases resembling coryza and others having headache, chills, fever, malaise, generalized diffuse pains, and rarely nausea, vomiting and a nonproductive cough During the course of the disease half of the patients had retrosternal and thoracic pain All had insomnia Physical signs were practically absent, except for slight pulmonary dullness, a small increase in the respiratory sounds, of a broncho vesicular nature, and heavy crepitus over the area where the x ray showed the presence of pneumonitis The pulse was full but with bradycardia in relation to the temperature All laboratory tests were negative, including those on blood, urine, sputum, cerebrospinal fluid, etc

The soft infiltrative lesion, single or multiple, and of a density not uniform as in lobar pneumonia, resembled on the x ray plate a patchy broncho pneumonia Pneumonitis occurred 5 times in the lower right pulmonary lobe, and in 2 patients more than one lobe was involved

In the outbreaks seen in Italy the disease had a sudden onset, with chills fever, sweating, general malaise, weakness, frontal headache, anorexia at times muscular aches, vague thoracic pains, at times pleural in nature, and diarrhea with abdominal cramps

Among the soldiers who became sick in the United States although they were infected in Italy there was a period of incubation not less than 13 days on the average In rather more than half of the cases the disease began gradually, in the rest, onset was sudden with a more acute beginning and more severe headache Many had a sensation of chilliness or frank chills muscular aches, and slight gastrointestinal and respiratory symptoms The average duration of the disease was 4 days but in 10 per cent of the cases it was 7 days Although febrile, the disease was benign in all

In the Fort Bragg laboratory outbreak, 14 of 16 patients had pneumonitis on x ray examination, and the average duration of the febrile period was from 7 to 10 days

Most of the Italian cases occurred in winter and spring

Complications

In 3 cases a severe meningismus was observed with no alterations in the spinal fluid

Mortality

A fatal termination of the disease is exceptional

Immunity

Convalescents, human or animal, develop immunity The presence of antibodies can be detected by laboratory methods (agglutination, comple

in the perivascular and pleural there are focal accumulations of carbon filled macrophages as well as lymphocytes and plasma cells Rarely large cells resembling the foreign body giant cell are seen in the exudate The spleen presents the picture of "acute splenic tumor" according to the description of Kneeland and Smetana

Summarizing the most important findings are

1 Nodular or confluent nodular hepatization with peribronchial or peribronchiolar localization

2 Alterations of the alveolar epithelium

3 Interstitial lymphocytic infiltration

4 Collapsed alveoli filled with polygonal epithelioid cells

5 The large blood vessels enveloped with a dense lymphocytic and at times monocytic sleeve

6 The pleura over the zone of hepatization shows stratified mesothelial proliferation and polynuclear neutrophilic infiltration

Since the end of World War II the publication of all the reports about the epidemics of so called "Balkan grippe" have added to our knowledge of "Q" fever This "grippe" was seen in the civilian population of Greece and in the armies of the United States England and Germany in both the Balkans and Italy and appeared as epidemic outbreaks of atypical pneumonia during 1944 and 1945 These outbreaks appeared to be different from influenza and Athens was suspected as being the source of the infection It was noteworthy that in an outbreak observed in Italy among a regiment of parachute troops the majority of cases occurred in a single company of the regiment also the outbreak was explosive with a case incidence of 30 per cent and there were no other associated respiratory diseases Caminopetros had isolated a strain of "Q" fever in Athens and had maintained it in guinea pigs for about a year without identifying it this being done subsequently by the Commission on Acute Respiratory Diseases In various epidemic outbreaks the cases were proved serologically *

Studies of Caminopetros (1948) showed that goats and sheep in the suburbs of Athens were infected and that the infection passed to the milk and was preserved by refrigeration Later investigations have shown that "Q" fever is endemic in Italy both in the north and south and in Corsica Returning troops gave origin to an outbreak in the United States in a bomber group in Virginia

Cheney and Geib (1946) proved the existence of "Q" fever in Panama

There is increasing interest in this disease in the United States Recent publications tell of the outbreak of 47 cases which occurred in February 1946 in Building No 5 of the National Institute of Health Thirteen cases had pneumonitis and 5 had bloody sputum The attenuated cases were more difficult to diagnose The Italian antigen proved useful in serologic studies Treatment was ineffective

*Editor's note (O F) Robbins et al (J Hyg 44 6 63 1946) described an explosive outbreak among troops in Italy suspected of being propagated by dust The transmission of Q fever by dried feces of naturally infested ticks on hides also must be considered especially in Australia

ment fixation protection tests) The appearance of antibodies may be late toward the end of the disease Immunologically all the strains of *R burneti* or *diaporica* so far isolated are equal differing however in virulence

Diagnosis

Diagnosis is based on the x ray detection of pneumonitis on isolation of the rickettsial agent in guinea pigs or mice and on serologic tests to show the presence of antibodies a method which also permits serologic investiga tion of groups

Differential Diagnosis

Differentiation must be made from all the pneumonitides or atypical pneumonias described as cited by Dyer (Bowen 1935 Allen 1936 1937 Bock 1938 Reimann 1938 Smiley 1939 Murray 1940 and especially Kneeland and Smetana and Longcope 1940) Pneumonitis caused by toxoplasmosis must also be considered (Pinkerton and Henderson 1941) At present isola tion of the causal agent is the most exact method of differentiation

Pathology

The preliminary studies of Burnet and Freeman (1937) on the micro scopic pathology of Q fever in experimentally infected mice have been amplified by the similar investigations of Lillie (1942) in guinea pigs of Findlay and Perrin and Bengtson (1942) in mice inoculated by the peritoneal or nasal route and by Lillie Perrin and Armstrong (1941) in monkeys *(Macaca mulatta)* and in man

In guinea pigs and mice the lesions depend largely on the route of inocu lation The two chief types of lesions are a focal perivascular lymphocytic ex udate and granulomas with giant cells having excentric nuclei The small pulmonary foci or nodules of hepatization present an alveolar exudate epithelioid cells and lymphocytic and monocytic interstitial infiltration and are very similar to although not identical with the foci of pneumonitis seen in man in which the alveolar exudate has much more abundant fibrin

Firm granular hepatization is found in man about as often as are foci of pneumonitis Congestion may occur in the rest of the lung and edema in 1 or more lobules The spleen is large with friable pulp The heart is dilated

On microscopic examination slides of the lung tissue correspond to the picture of pneumonitis described by Kneeland and Smetana (1940) In the zone of hepatization the alveoli bronchioles and part of the bronchi are oc cluded by compact fibrinocellular exudate The cells consist of lympho cytes plasma cells large mononuclears and erythrocytes At times pyknotic elongated nuclei fibroblasts and bits of desquamated alveolar epithelium are found In the denuded area the exudate appears to adhere to the alveolar wall Polynuclear neutrophiles are scarce or absent Interalveolar septa are scarcely thickened and present accumulations of lymphoid and plasma cells and large mononuclears The capillaries contain but little blood there is al ways some *degree of fibrosis In the peribronchial* connective tissue, as well as

cases occurred as well in Mesopotamia and in Egypt. It did not assume importar during World War II although a few cases were reported. Pechtel and Werner (19 and Peña Yanez (1940) cite cases.

Etiology

The specific cause of quintana fever has been much discussed, the infectious age has not been clearly established. It is known that the blood of those suffering from t disease is infectious for healthy men from a few hours *after the appearance of clin* symptoms until about 450 days later in the exceptional cases of such long duration a that infectiousness is permanent even in the intervals between febrile bouts.

The presence of *R. quintana* in lice fed on the sick, and its absence in healthy lic *its appearance in lice between the fifth and the eighth day after ingestion of infectio* blood and its progressive increase in the feces during the following days, the lack pathogenicity of the rickettsia for lice and the duration of the infection during the li of the louse, its nonhereditary character and the parallelism between infectiousness t *presence of virus and of the rickettsias in the lice like the parallelism between t* mechanism of infection of trench fever and exanthematic typhus fever (lice feces spre over the bites, abrasions of skin, or conjunctiva), elimination of the virus in urine (as murine typhus)—all suggest that *R. quintana* is quite possibly the specific agent of t *disease, although, as in other rickettsial diseases, it has not been demonstrated directly* infectious material of human origin, including blood. The negativity of the Weil-Fel reaction, the lack of pathologic findings, the lack of reaction in laboratory animals inoculat experimentally with the virus, and the lack of recent outbreaks all are factors which, tak *together, leave this problem without an immediate solution.*

Munk and da Rocha Lima and Sikora found *R. pediculi*—nonpathogenic and ind tinguishable from *R. quintana*—in lice fed on healthy individuals. The large number asymptomatic cases and the prolonged duration of the virus in convalescents or in chron cases, the existence of a certain apparent racial immunity in countries with much pediculos the prolonged infectiousness of the louse feces for 4 or more months after excretion, and th high resistance of the virus to external physical agents suggest the necessity of cautic in deciding against the identity of the two rickettsias. Even the different degree of virulen shown in each may have another explanation than those put forward by *the opponents* the theory of the rickettsial etiology of trench fever, which arguments may be summarize as follows: *R. quintana* is identical with *R. pediculi* and since the latter occurs in norm lice fed on normal individuals, the presence of the former in cases of trench fever lac etiologic significance, *another agent being the true cause of the disease.*

Epidemiology

From the foregoing many considerations can be involved on the ep demiology of this disease. It is worth while to recall that the louse is the onl important agent in the transmission of the disease, and the convalescent car rier, or the inapparent case, the principal reservoir. In exanthematic typhu fever the louse does not act as a reservoir because the rickettsial infection i fatal for it; in trench fever the louse is not affected by the virus and main tains it for the rest of its life. It follows that the louse is also an importan *reservoir of virus—a terminal reservoir*, since the infection is not hereditary Excreta of infected lice are the immediate source of human infection and blood of the sick is the source of the infection in lice.

The disease has the same general epidemiology as human exanthemati typhus—i.e., it is favored by war, famine, misery, crowding, cold, associatio of sick and well—by all the factors which favor lousiness. But the carrier

The detailed report of the outbreak in Amarillo, Texas, in 1946 (Topping et al, 1947), described 55 cases, with 2 deaths There were 136 employees in the 3 branches of the involved abattoirs

In August, 1946, Shepard reported 33 cases of " Q" fever among 81 employees in a Chicago packing house The average incubation period was 19 to 25 days

Huebner et al (1948) report 17 cases in Los Angeles County and 100 additional cases in southern California related to infection in cattle (10 to 20 per cent of the cows), from which 4 strains of *R burneti* were found in 4 different dairies Oliphant and Parker report 3 additional cases of laboratory infections in 1948 Huebner, Hottle, and Robinson (1948) tried out streptomycin in experimental infection of chick embryos with " Q" fever, with mediocre results

II THE RECURRENT RICKETTSIOSES

2 TRENCH FEVER

Synonyms —Wolhynian fever, quintana or five day fever, funftagefieber, pyrexia of unknown origin, Meuse fever, shin fever

Definition

An infectious febrile disease, of recurrent character, possibly caused by *R quintana (wolhynica)* and transmitted from man to man principally by the human louse (*Pediculus corporis* and *Pediculus v capitis*)

Characteristics

Recurrent pyrexia with an incubation period varying from 1 week to 1 month following which there supervenes a series of as many as 10 to 12 febrile paroxysms (average 4 to 6), with an individual duration of 20 to 30 hours exacerbations which are accompanied by chills fever, and sweating During the clinical course there are signs of grippe various pains splenomegaly changes in sensibility evanescent exanthematic eruptions, and moderate leucocytosis It is stated that the Weil Felix reaction is negative The course of the disease is prolonged convalescence is long and stormy and subsequent immunity is transitory Mortality is nil

Incidence and Geographic Distribution

Trench fever was a disease peculiar to World War I It is possible that the epidemics of ' military sweating ' described during the previous century had the same etiology In 1915 it was observed in epidemic form in Poland and Volhynia being described by His and Werner in the German Army Graham Hunt, and Rankin and McNee, Brunt, and Henshaw (who named it trench fever) saw it on the Allied front The reports of the American and English commissions presided over by Strong and Byam, respectively, are the most valuable sources of information on the disease, and from these we have taken the data which follow Byam estimates that during 4 years there were about 800 000 cases among the Allied troops Strong believes that between one third and one fifth of all cases of sickness among the combatants were due to trench fever It occurred in epidemic form in Flanders France Poland, Galicia Bukovina Italy, Salonica, and Macedonia, and

3 RICKETTSIOSIS (RICKETTSIEMIA) WEIGLI

Mosing (1936) described an epidemic of a relapsing fever resembling trench fever among the workers in the laboratory of Professor Weigl who were in charge of feeding the lice used in the preparation of the vaccine of this investigator It is supposed that the infectious agent is a rickettsia called *R weigli* The disease is a septicemia which has no relation to exanthematic typhus The relationship of *R weigli* with *R quintana* and *R pediculi* has not been determined Some writers suggest that these are attenuated forms of trench fever

R weigli is differentiated from *R prowazeki* by its larger size extra cellularity and nonpathogenicity for lice

Other authors mention similar epidemic outbreaks under similar conditions but more exact studies on this matter are lacking

III PETECHIAL EXANTHEMATIC RICKETTSIOSES

4 EXANTHEMATIC TYPHUS

From the clinical point of view there are no differences between human typhus transmitted by lice and murine typhus transmitted by fleas A separate clinical description of the latter would duplicate, along general lines moderate cases of the former

On the other hand, the diseases are epidemiologically different and thus a separate description is required for each disease The differentiation of the virus based on experimental methods and laboratory tests, has been described in the general section

Synonyms—Of the 80 or more terms applied to classical exanthematic typhus and of the 50 used to designate murine typhus mention will be made only of those most frequently used

Murine Typh [illegible] Tolan
typhus of Bangalo [illegible]
of Saigon Cholon [illegible]
urban endemic of [illegible]
fever, flea typhus rat disease of Toowoomba, typhus minor, ancestral orchitis, [illegible]
fever, estival nondiffusible dermotyphus, sporadic typhus of Tonkin, Maxcy's disease
Hone's disease intermediate minor, murine, or endemic rickettsiosis

Classical Typhus—Human typhus, humanized, European, Old World, *historical*, *major*, epidemic, ataxic petechial fever, tabardillo, pintas, dermotyphus Brill s disease is a sporadic form of classical typhus and must not be confused with the endemic murine typhus of the southeastern United States

Definition

Typhus is a disease caused by *R prowazeki* or *R mooseri* and transmitted from man to man by the human louse and from rat to man by rat fleas, especially *Xenopsylla cheopis* It is not possible clinically to define the etiologic agent in the absence of epidemiologic or experimental data

and inapparent cases on the one hand and the volume of susceptible population and the degree of lousiness on the other are the factors which determine the epidemic or endemic evolution of the disease

Clinical Description

The incubation period is generally asymptomatic with prodromal symptoms (headache malaise restlessness insomnia) Toward the end of this period which on the average is 10 to 20 days in duration (6 to 7 days in cases of experimental infection caused by inoculation of the virus and 30 or more when the disease is transmitted by lice) the disease proper begins either suddenly or gradually

In grave cases the onset is abrupt the illness may begin when the individual is in the midst of his normal occupation and he may suffer an actual collapse Early dizziness may impede walking Onset is accompanied by chills and rarely by nausea and vomiting In a few hours the temperature reaches 39 5° or 40° C (103 104° F) The fever curve later assumes one of the following three types

1 Fever of about 3 days duration followed by recovery

2 Initial fever followed by an afebrile period and later with new exacerbations of temperature up to 12 or more (4 to 6 on the average) febrile recurrences which may show regular 5 to 7 day intervals of apyrexia or irregular periods of apyrexia

3 More or less continuous irregular fever in which an elevation of temperature is incorporated with the developments described below without any intervening period of normal temperature

On the second or third day or later and sometimes at the time of the second rise of fever there develops an evanescent exanthem in 5 per cent of cases according to Haagen more frequently according to others This lasts 6 to 48 hours and consists of a few to many (up to 200) pink spots of uniform size varying from 2 to 4 mm up to 6 to 8 mm in diameter appearing only on the chest back and abdomen and disappearing without residues These roseolas are macular rarely papular still more seldom vesicular and they always become pale on pressure

During the course of the disease the pulse is accelerated in proportion to the temperature alterations corresponding to paroxysmal tachycardia being noted and often especially in cases of slow evolution accentuated cardiac irregularities Systolic arterial pressure is high Respiration is normal unless there is an effort dyspnea

From the beginning of the disease intense headache is observed principally frontal at other times intracranial rarely parietal or occipital and there are retro orbital pains One of the characteristics of the disease is the generalized aching which after the first attack becomes localized in various sites especially in the lower extremities and changing in location from day to day These pains are osseous cartilaginous muscular tendinous articular etc and may be continuous or abrupt and transitory but in all cases they are more

occur but the persistence of the virus in the flea during the life of the latter inclines one to think that the usual situation is one of typhus endemicity among the rodents In man epidemiologic conditions cause what seems to be endemicity but in reality only sporadic cases of murine typhus occur in man Now if this typhus becomes epidemic it will resemble classical typhus and therefore does not merit separate consideration It must be especially noted that some writers such as Megaw, believe that humanization and epidemization of murine typhus probably does not occur, and that in those countries in which this phenomenon is described it is more likely that both types of typhus exist independently and simultaneously

Whatever the relation is between murine and classical typhus these can be described in relation to man in their most definite and peculiar epidemiologic manifestations

(a) **Murine Typhus** —Murine typhus in man as studied by Maxcy in the southern part of the United States has the following epidemiologic characteristics

1 Sporadic incidence especially in the fall

2 No relationship in the sense of contagion between cases

3 Absence of lice as vectors

4 Greater incidence in men than in women and children
